   - Chest (sounds of wheezing during normal breathing or prolonged phase of forced exhalation, hyperexpansion of the thorax, use of accessory muscles, appearance of hunched shoulders, chest deformity); and
   - Skin (atopic dermatitis, eczema).
3. Spirometry can demonstrate obstruction and assess reversibility in patients of more than 5 years of age. Patients' perceptions of airflow obstruction are highly variable. Spirometry is an essential objective measure to establish the diagnosis of asthma, because the medical history and physical examination are not reliable means of excluding other diagnoses or of assessing lung status. Spirometry is generally recommended, rather than measurements by a peak flow meter, due to wide variability in peak flow meters and reference values. Peak flow meters are designed for monitoring, not as diagnostic tools.

   A differential diagnosis of asthma should be considered. Recurrent episodes of cough and wheezing most often are due to asthma in both children and adults; however, other significant causes of airway obstruction leading to wheeze must be considered both in the initial diagnosis and if there is no clear response to initial therapy.
4. Additional studies are not routinely necessary, but may be useful when considering alternative diagnoses.
5. Additional pulmonary function studies, such as diffusing capacity, measures of lung volumes and evaluation of inspiratory flow-volume loops will help if there are questions about other diseases such as a restrictive defect, vocal cord dysfunction or bullous lung diseases.
6. Bronchoprovocation with methacholine, histamine, cold air or exercise challenge may be useful when asthma is suspected and spirometry is normal or near normal. For safety reasons, bronchoprovocation should be carried out only by a trained individual. A positive test for airway hyperresponsiveness, which is a characteristic feature of asthma is diagnostic, but

can also be present in other conditions. Thus, a positive test is consistent with asthma, but a negative test may be more helpful to rule out asthma.

7. Chest X-ray may be needed to exclude other diagnoses.
8. Biomarkers of inflammation are currently being evaluated for their usefulness in the diagnosis and assessment of asthma. Biomarkers include total and differential cell count and mediator assays in sputum, blood, urine and exhaled air.

Common Diagnostic Challenges

1. Cough Variant Asthma: Cough can be the principal or only manifestation of asthma, especially in young children. Monitoring of Peak Expiratory Flow (PEF) or bronchoprovocation may be helpful. Diagnosis is confirmed by a positive response to asthma medications.
2. Vocal Cord Dysfunction (VCD), which is seen commonly in adolescent girls, can mimic asthma, but it is a distinct disorder. Vocal cord dysfunction may coexist with asthma. Asthma medications typically do little to relieve VCD symptoms. Variable flattening of the inspiratory flow loop on spirometry is strongly suggestive of VCD. Diagnosis of VCD is made from indirect or direct vocal cord visualization during an episode, during which the abnormal adduction can be documented. VCD should be considered in difficult-to-treat, atypical asthma patients and in athletes who have exercise-related breathlessness unresponsive to asthma medication.
3. Gastroesophageal Reflux Disease (GERD), Obstructive Sleep Apnea (OSA) and Allergic Bronchopulmonary Aspergillosis (ABPA) may coexist with asthma and complicate diagnosis.
4. Children in the age group of 0 to 4 years pose particularly a challenge. Diagnosis in infants and young children is elusive, complicated by the difficulty in obtaining objective measurements of lung function in this age group. Caution is needed to avoid giving inappropriate, prolonged asthma therapy. However, it is important to avoid under-diagnosing asthma by using such labels as "wheezy bronchitis," "recurrent pneumonia," or "Reactive Airway Disease (RAD)," thereby missing the opportunity to treat a child. The chronic airway inflammatory response and structural changes that are characteristic of asthma can develop in the preschool years, and appropriate asthma treatment will reduce morbidity.

Guideline-Based Management of Asthma

National Asthma Education and Prevention Program (NAEPP) is dedicated to translating research findings into clinical practice. The first NAEPP guidelines were published in 1991, and updates were made in 1997, 2002 and in 2007. Important gains have been made in reducing morbidity and mortality rates due to asthma; however, challenges remain. Several guidelines have been made in India for adults as well as for children.

The goal of NAEPP, EPR3 2007 guideline,[7] is to help people with asthma control their disease so that they are active all day and sleep well at night. New focus of management is on monitoring asthma control as the goal for asthma therapy and distinguishing between classifying asthma severity and monitoring asthma control (Fig. 74.1). The impairment and the risk are the two key domains of assessment of severity and control. The domains represent different manifestations of asthma, they may not correlate with each other, and may respond differentially to treatment. Impairment represents the frequency and intensity of symptoms and functional limitations, the patient is experiencing currently or has recently experienced. Risk represents the likelihood of either asthma exacerbations, progressive decline in lung function or for children, lung growth; or risk of adverse effects from medication. Modifications have been made in the stepwise approach to managing long-term asthma.

Treatment recommendations are presented for three age groups (0–4 years of age, 5–11 years of age, and youths more than 12 years of age and adults) because of several different reasons:

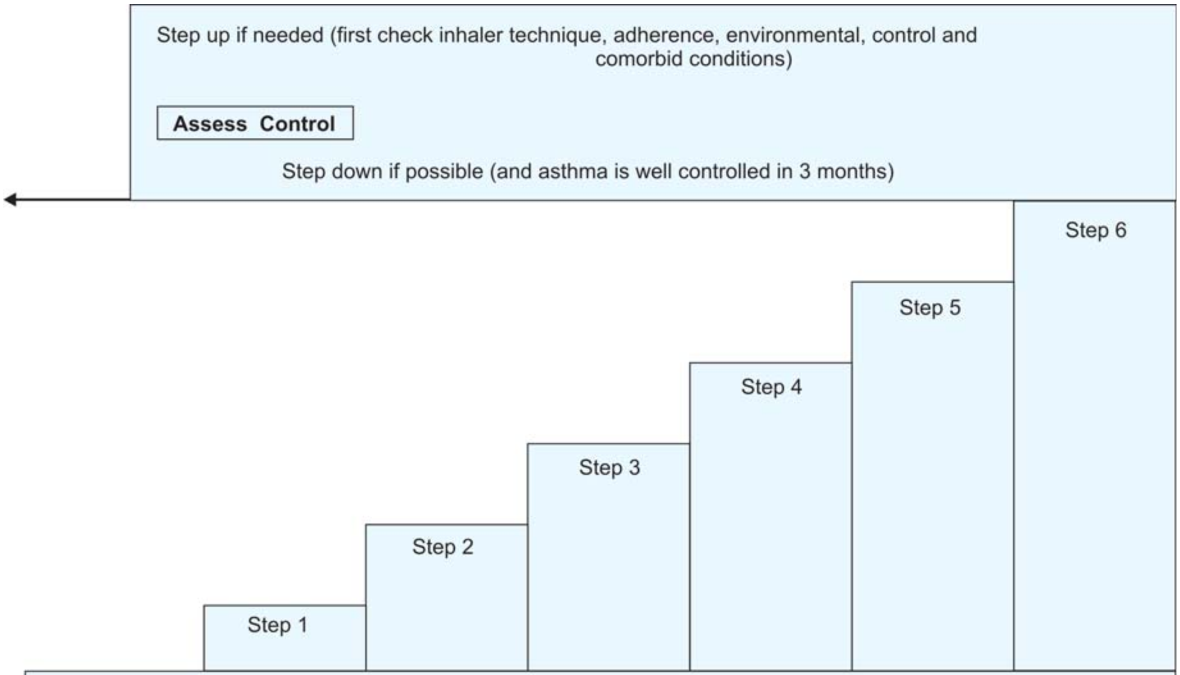
i. The course of the disease may change over time;
ii. The relevance of different measures of impairment or risk and the potential short- and long-term impact of medications may be age related; and
iii. Varied levels of scientific evidence are available for these three age groups.

The stepwise approach expands to six steps to simplify the actions within each step (Fig. 74.2). Previous guidelines had several progressive actions within different steps; these are now separated into different steps. Medications also have been repositioned within the six steps of care. The new emphasis is made on multifaceted approaches to patient education and to the control of environmental factors or comorbid conditions that affect asthma. Modifications to treatment strategies for managing asthma exacerbations have also been improvised.

Components of severity		Assessing asthma control and adjusting therapy in children					
		Well controlled		Not well controlled		Very poorly controlled	
		Ages 0–5	Ages 5–11	Ages 0–5	Ages 5–11	Ages 0–5	Ages 5–11
Impairment	Symptoms	≤ 2 days/week. But not more than once on each day		2 days/week or multiple times on < 2 days/week		Throughout the day	
	Night-time awakenings	≤ 1x/month		>1x/month	≥ 2x/month	>1x/week	≥ 2x/week
	Interference with normal activity	None		Some limitation		Extremely limited	
	Short-acting beta$_2$-agonist use for symptom control (Prevention for EBI)	≤ 2 days/week		>2 days/week		Several times per day	
	Lung function • FEV_1 predicted or peak flow (Personal best) • FEV_1/FVC	N/A	> 80% > 80%	N/A	60-80% 75-80%	N/A	< 60% < 80%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1x/year		> 2–3x/year	> 2x/year	> 3x/year	≥ 2x/year
	Reduce in lung growth	N/A	Requires long-term follow-ups	N/A		N/A	
	Treatment related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.					
Recommended action for treatment (see "Stepwise Approach for Managing Asthma" for treated steps) The stepwise approach is meant to assist, not replace the clinical decision making required to meet individual patient needs.		• Maintain current step • Regular follow-up every 1–6 months • Consider step down if well controlled for at least 3 months.		Step up 1 step	Step up at least 1 step	• Consider short course of oral systemic corticosteroids • Step up 1–2 steps.	
				• Before step up: Review adherence to medication, inhaler technique and environmental control. If alternative treatment was used, discontinue It and use preferred treatment for that step. • Re-evaluate the level of asthma control in 2–6 months to achieve control, every 1–6 months to maintain control. Children 0–4 years old: if no clear benefit is observed in 4–6 weeks, consider alternative diagnoses or adjusting therapy. Children 5–11 years old: Adjust therapy accordingly. • For side effects, consider alternative treatment options.			

Adapted from EPR 3 guidelines for asthma

Fig. 74.1: Assessing asthma control and adjusting therapy in children



Step up if needed (first check inhaler technique, adherence, environmental, control and comorbid conditions)
Assess Control
Step down if possible (and asthma is well controlled in 3 months)
Step 6
Step 5
Step 4
Step 3
Step 2
Step 1

Children 0–4 Years of Age						
	Intermittent Asthma	Persistent Asthma: Daily Medication Consult with Asthma Specialist if step 3 care or higher is required: consider Consultation at step 2				
Preferred	SABA PRN	Low dose ICS	Medium dose ICS	Medium dose ICS + LABA or montelukast	High dose ICS + LABA or montelukast	High dose ICS + LABA or Montelukast + oral corticosteroids ICS
Alternative		Cromotyn or Montelukast				
	Each step: Patient education and environmental control					
Quick-relief medication	• SABA as needed for symptoms: Intensity of treatment depends on severity of symptoms. • With viral respiratory symptoms: SABA q 4–6 hours up to 24 hours (longer with physician consultation). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations. Caution: Frequent use of SABA may indicate the need to step up treatment. See next for recommendation initiating long-term-control therapy.

Children 5–11 Years of Age

	Intermittent Asthma	Persistent Asthma: Daily Medication Consult with Asthma Specialist if step 3 care or higher is required: consider Consultation at step 2				
Preferred	SABA PRN	Low dose ICS	Low dose ICS + LABA, LTRA or Therapyline	Medium dose ICS + LABA	High dose ICS + LABA	High dose ICS + LABA + oral corticosteroids
Alternative		Cromotyn LTRA Nedocromil or Therapyline	Medium dose ICS	Medium dose ICS + LTRA or Therapyline	High dose ICS + LTRA or Therapyline	High dose ICS + LTRA + oral corticosteroids
	Each Step: Patient Education and Environmental Control and Management of Comorbidities Step 2-4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma					
Quick-relief medication	• SABA as needed for symptoms: Intensity of treatment depends on severity of symptoms: up to 3 treatment at 20-minutes intervals as needed. Short course of oral systemic corticosteroids may be needed. Exacerbation is severe or patient has history of previous severe exacerbations. Caution: Increase use of SABA or use > 2 days a week for symptoms relief (no prevention of EIB) generally indicates inadequate control and the need to step up treatment					

Fig. 74.2: Step-wise approach for managing asthma in children, 0–4 years and 5–11 years of age

Management

Goal of Therapy: Control of Asthma

a. *Reduce impairment*

- Prevent chronic and troublesome symptoms (e.g. coughing or breathlessness in the daytime, in the night, or after exertion)
- Require infrequent use (≤ 2 days a week) of inhaled Short-Acting Beta Agonists (SABA) for quick relief of symptoms [not including prevention of Exercise-Induced Bronchospasm (EIB)]
- Maintain (near) normal pulmonary function
- Maintain normal activity levels (including exercise and other physical activity and attendance at school or work)
- Meet patients' and families' expectations of and satisfaction with asthma care.

b. *Reduce risk*

- Prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations
- Prevent loss of lung function; for children, prevent reduced lung growth
- Provide optimal pharmacotherapy with minimal or no adverse effects of therapy.

Achieving and Maintaining Asthma Control Requires Four Components of Care

1. Assessment and monitoring.
2. Education for a partnership in care.
3. Control of environmental factors and comorbid conditions.
4. Medications.

A step-wise approach to asthma management incorporates these four components, emphasizing that pharmacologic therapy is initiated based on asthma severity and adjusted (stepped up or down) based on the level of asthma control. Special considerations of therapeutic options within the stepwise approach may be necessary for situations such as Exercise-Induced Bronchospasm (EIB), surgery and others. This approach is used for assessing a patient's overall asthma severity, once the most optimal asthma control is achieved and maintained, or for population-based evaluations.

Allergic Bronchopulmonary Aspergillosis

Ritesh Agarwal

INTRODUCTION

Allergic Bronchopulmonary Aspergillosis (ABPA) is a complex immunological pulmonary disorder caused by hypersensitivity to *Aspergillus* species mainly *Aspergillus fumigatus*, with resultant systemic immune activation, chronic asthma, recurrent pulmonary infiltrates and bronchiectasis.[1,2] Allergic aspergillosis primarily complicates the course of patients with bronchial asthma and Cystic Fibrosis (CF).[3] The disease remains underdiagnosed in many countries, and as many as one-third of all cases are initially misdiagnosed as pulmonary tuberculosis in the developing countries.[4-7] The condition has immunologic features of immediate hypersensitivity (type I), antigen-antibody complexes (type III), and eosinophil-rich inflammatory cell responses (type IVb), based on the revised Gell and Coombs classification of immunologic hypersensitivity.[8, 9] The disorder was first described by Hinson in 1952 in the United Kingdom,[10] in 1957 in Australia[11] and in 1958 in the United States.[12] From India, the first case was described in 1971.[13] The disease presents with varied clinical and radiological manifestations ranging from an asymptomatic patient with or without pulmonary infiltrates to severe uncontrolled asthma with or without Central Bronchiectasis (CB) and pulmonary fibrosis.[14-21] A lung biopsy is generally not required, and the diagnosis can often be made on clinical, radiologic and serologic grounds. An early diagnosis is not difficult in the presence of an increased clinical suspicion. However, there are reports of mean diagnostic latency of as long as 10 years between the occurrence of first symptoms and the diagnosis.[22] In the past two decades, there has been an increase in the number of cases possibly due to the heightened physician awareness and the availability of serologic assays for the diagnosis of ABPA.[4-6,23,24] This chapter summarizes the current concepts in the pathogenesis, diagnosis and management of this complex entity.

Characterization of Aspergillus Species

Aspergillus was first catalogued in 1729 by the Italian priest and biologist Pietro Antonio Micheli and the species *Aspergillus fumigatus* was described in 1863 by Johann Baptist Georg Wolfgang Fresenius. There are approximately 250 species of *Aspergillus*, but only a few are known to be pathogenic for humans.[25] *A. fumigatus*, *A. flavus*, and *A. niger* are the most commonly encountered pathogenic species.[26] It is of interest to note that only pathogenic species (for example, *A. fumigatus*, *A. flavus* and others) can grow at body temperature. *Aspergillus* is a ubiquitous mold found in organic debris, dust, compost, foods, spices and rotted plants. It is also one of the most common indoor molds especially in the attics and basements, bedding, curtains, floor mats and house dust. Worldwide surveys have found that *Aspergillus* species represent between 0.1% and 22% of the total air spores sampled.[27] *Aspergillus* species are thermotolerant and capable of growing at a wide range of temperatures. These fungi can be cultured using Sabouraud's agar medium at 37°C in contrast to many other fungi whose growth is inhibited beyond 35º Celsius. The spores of *A. fumigatus* (2 to 3.5 µm in size) are in the respirable range, and can thus easily enter the airways. In susceptible persons, spores germinate into hyphae, which colonize the bronchi. *Aspergillus* is recognized by its filamentous, septate hyphae appearance of approximately 3 to 7 µm wide with Y-shaped branching in tissue preparations.

The clinical, radiological and histological manifestations of bronchopulmonary aspergillosis are due to a complex interplay between the number and virulence of the organisms and the patient's immune response.[28] Depending on the host immunity and the organism virulence, *Aspergillus* can cause a variety of respiratory diseases, which include simple colonization, aspergilloma, hypersensitivity pneumonitis, Immunoglobulin E (IgE)-dependent asthma, severe asthma with fungal sensitization, ABPA, chronic necrotizing pulmonary aspergillosis, invasive airway aspergillosis and invasive pulmonary aspergillosis.[29-31] ABPA is currently the best recognized manifestation of *Aspergillus*-associated hypersensitivity disorders. An ABPA-like syndrome can also be caused by numerous fungi other than *A. fumigatus*, and is known as Allergic Bronchopulmonary Mycosis (ABPM).[32]

EPIDEMIOLOGY OF ABPA

Aspergillus hypersensitivity (AH) is defined as the presence of an immediate-type cutaneous hypersensitivity to commercial (or an indigenously prepared) extracts of *Aspergillus* or an increase in *Aspergillus*-specific IgE levels.[33] ABPA can be conceptualized as an exaggerated form of AH, and AH is currently considered as the first step in the development of ABPA.[34] However, only a small proportion of patients with AH develop the complete clinical picture of ABPA.[5-7,34] Despite the numerous published case series on ABPA, the exact prevalence of AH and/or ABPA in patients with bronchial asthma remains unknown.[35] The prevalence of AH is difficult to ascertain due to the variability of the skin tests (intracutaneous vs prick tests), the diverse antigens (commercial vs locally prepared) used for the performance of these skin tests, the lack of standardized diagnostic criteria and the absence of optimum disease-specific cut-off values for various serological tests that are used. The incidence of AH is not clear because of the lack of population-based data for this purpose. The population prevalence of ABPA is generally stated to be about 1 to 2% in patients with bronchial asthma and 2 to 15% in patients with CF.[2,21,36,37] The population prevalence of ABPA in asthma is based on the inference of three studies (one peer-reviewed and two non-peer reviewed studies), and may not be entirely correct.[38,39] In the only peer-reviewed study, 14 patients with allergic bronchopulmonary mycosis were identified from a total of 1,390 new referrals in a catchment area population of around half a million, estimating a period prevalence of just above 1%.[38] In a questionnaire-based study carried out in 2.4 million people (Orange County, California), there were 143 cases of ABPA under the care of pulmonary and allergy specialists.[39] In another analysis conducted in 1991, the ABPA Committee of the American Academy of Allergy, Asthma and Immunology (AAAAI) performed a survey among the members of academy to find the number of ABPA cases under their treatment. Of the 33% respondents, it was observed that 703 patients with ABPA were under current care, and other physicians shared 49% of them. If the same case rate is assumed amongst non-respondents, then this figure might increase to 2,000. Both the above surveys from the United States projected the maximum number of ABPA patients as around 11,000, which in 1991 (in the 260 million US population), represented 1% of the estimated 12 million asthma patients in the United States.

The prevalence of ABPA in patients with asthma is likely to be much higher than currently believed. In a recently published systematic review, we demonstrated a pooled prevalence of AH and ABPA of 28% (95% CI, 24 to 34) and 12.9% (95% CI, 7.9 to 18.9) respectively.[35] The only limitation of this analysis was that all studies were performed in specialized chest or asthma clinics, which represent a selection bias as only the most symptomatic patients are likely to reach these clinics, and thus does not represent the population prevalence of ABPA. The prevalence of ABPA in bronchial asthma reported in six large studies in the last decade is summarized in Table 75.1.[6,7,40-43] The prevalence of AH and ABPA is even higher in patients with severe acute asthma. In a recent study of 57 patients with severe acute asthma admitted to a respiratory intensive care unit, we found the prevalence of AH and ABPA of around 51% and 39% respectively compared to the outpatient bronchial asthma prevalence of 39% and 21% respectively.[44]

TABLE 75.1: Studies describing the prevalence of *Aspergillus* hypersensitivity and/or allergic bronchopulmonary aspergillosis in patients with bronchial asthma over the last decade

Study	*Type of study*	*Type of skin test*	*Type of antigen*	*Criteria used for diagnosis of ABPA*	*Prevalence of AH in asthma (n/N)*	*Prevalence of ABPA in asthma (n/N)*

Criteria for ABPA-Major (A-asthma, R-radiologic opacities, T-immediate positive skin test, E-eosinophilia, P-precipitins to *A. fumigatus*, I-IgE elevated, C-central bronchiectasis, S-specific IgG/IgE to *A. fumigatus*); Minor (C-sputum cultures of *A. fumigatus*, S-type III skin test positivity, B-brownish black mucus plugs)

PATHOGENESIS OF ABPA

The reason why only a minority of asthmatics develop ABPA is not fully understood.[3] In healthy individuals, *Aspergillus* is rapidly cleared by alveolar macrophages utilizing oxidase-dependent killing mechanisms.[45] Exposure to high concentrations of *A. fumigatus* spores from garbage dump sites, agricultural conditions, bird droppings and smoking moldy marijuana have been reported to cause ABPA.[10,46-49] Environmental factors are however, currently not considered to be the main pathogenetic factors in causation of ABPA because not all asthmatics develop ABPA despite being exposed to the same environment. It is likely that on a background of genetic susceptibility,[50-62] (Table 75.2), inhaled conidia of *A. fumigatus* and occasionally other fungi are able to germinate, leading to the growth of hyphae in mucus plugs. The fungi release antigens and exoproteases that compromise mucociliary clearance, stimulate and breach the airway epithelial barrier and activate the innate immune system of the lung, including the epithelial and the alveolar production of several inflammatory cytokines.[63-66] This leads to influx of the inflammatory cells, including the neutrophils and the eosinophils with resultant early and late-phase inflammatory reactions.[67,68] The antigens are further processed by the antigen-presenting cells and presented to T-cells. There is activation of both Th1 and Th2 responses, but heavily skewed towards a Th2 CD4+ T-cell response with release of IL-4, IL-5 and IL-13.[50,69-71] The Th2 cytokines lead to total and *A. fumigatus*-specific IgE synthesis, mast cell degranulation and promotion of a strong eosinophilic response. The inflammatory cells (partly contributed by fungal proteases) lead to tissue injury and the characteristic pathology of ABPA. In fact, animal models suggest the necessity of both IgE and IgG anti-*Aspergillus* antibodies in the pathogenesis of the disease.[72,73]

TABLE 75.2: Genetic factors associated with allergic bronchopulmonary aspergillosis

- Presence of HLA DR-2 and absence of HLA-DQ2 sequences[50,52,53]
- Interleukin 10 promoter polymorphisms[57]
- Surfactant protein A gene polymorphisms[56,61]
- CFTR gene mutation[51,54,55]
- Interleukin 15 polymorphisms[60]
- Tumor necrosis factor-α polymorphisms[60]
- Mannose-binding lectins polymorphisms[61]
- Interleukin 4 receptor polymorphisms[59]
- Interleukin 13 polymorphisms[58]
- Toll-like receptor gene polymorphisms[62]

PATHOLOGY OF ABPA

The pathology of ABPA varies from patient-to-patient (Table 75.3) and is different in different areas of the lung in the same patient.[74] Although the clinical picture of ABPA is well documented, detailed information is not available on its pathology, which reflects the fact that the diagnosis is primarily based on the serology and only a minority of patients requires lung biopsy. The finding of proximal bronchiectasis, i.e. the involvement of segmental and subsegmental bronchi with sparing of the distal branches is typical of ABPA.[75] The bronchi are filled with thick tenacious mucus plugs of dense

TABLE 75.3: Pathologic findings encountered in allergic bronchopulmonary aspergillosis

- Bronchiectasis involving segmental and subsegmental bronchi with sparing of distal bronchi
- Eosinophilic pneumonia
- Eosinophilic bronchitis
- Granulomatous bronchiolitis or bronchocentric granulomatosis
- Bronchiolitis obliterans with organizing pneumonia
- Localized tissue invasion by *A. fumigatus* without vascular invasion

eosinophilic material with many cells and granular debris. Histopathological examination reveals the presence of mucus, fibrin, Curschmann's spirals, Charcot-Leyden crystals and inflammatory cells. Scanty hyphae can often be demonstrated by in the bronchiectatic cavities. The bronchial wall in ABPA is usually infiltrated by inflammatory cells, primarily the eosinophils.[75] The peribronchial parenchyma contains a mixed chronic inflammatory response, often with conspicuous eosinophilia. Recurrent or transient parenchymal opacities are generally the result of an eosinophilic pneumonia. Occasionally, fungal growth in the lung parenchyma can occur in some patients with ABPA.[76] Patients can also demonstrate a pattern similar to that of bronchiolitis obliterans with organizing pneumonia.[77] A prominent feature is the presence of noncaseating granulomatous inflammation containing eosinophils and multinucleated giant cells centered on the airways, referred to as bronchocentric granulomatosis.[78,79] Fungal hyphae may be identified in the centers of some granulomas in the peribronchial tissue. The pathologic appearance is quite distinct from that of necrotizing pneumonia with vascular invasion described in patients with invasive aspergillosis. In patients with ABPA and localized tissue invasion, the host response seems to be able to limit the growth of the fungus and severe tissue destruction does not occur. Rarely, cases of invasive aspergillosis complicating the course of ABPA have been described in the literature.[80-85]

Clinical Features

Most patients are diagnosed in the third to fourth decades, and there is no gender predilection.[86] Although the initial descriptions involved mainly adults, an increasing awareness of the disorder by both the pulmonary and the nonpulmonary physicians has led to recognition of the disease in infancy[87] and early childhood.[88] The clinical features of ABPA encountered in three large series[4,6,7] published from the author's institute are summarized in Table 75.4. Patients are generally symptomatic with low-grade fever, wheezing, bronchial hyperreactivity, hemoptysis or productive cough. One clinical clue to the diagnosis of ABPA is the presence of asthma, which is poorly controlled with drugs.[89, 90] Patients can also present with the episodes of systemic illness with fever, weight loss and malaise. Expectoration of brownish black mucus plugs believed to a characteristic symptom is seen in 31 to 69% of patients.[4,6,41] The symptoms of hemoptysis and expectoration of brownish-black mucus plugs and a history of pulmonary opacities in an asthmatic strongly points towards the diagnosis of ABPA. However,

Central bronchiectasis	69%	76%	82%

patients with ABPA can often be asymptomatic and the disorder is diagnosed on routine screening of apparently well controlled asthmatics.[5,6,40] In a series of 155 cases of ABPA, almost 19% of patients with ABPA had well controlled asthma, and ABPA should be suspected in all asthmatics whatever the severity.[5,6] There are no characteristic findings on physical examination. Physical examination can be normal or may reveal findings of polyphonic wheeze. Clubbing is seen in only 16% of patients, usually those with long-standing bronchiectasis. On auscultation, coarse crackles can be heard in 15% of patients.[6] Wheeze on physical examination and pulmonary opacities on chest radiograph may suggest ABPA. Physical examination also detects complications of ABPA such as pulmonary hypertension and/or respiratory failure. During exacerbations of ABPA, localized findings of consolidation (localized crackles, bronchial breath sounds) and atelectasis (diminished breath sounds) can occur and needs to be differentiated from other pulmonary diseases. Clinically, it is often difficult to differentiate these conditions based on clinical assessment alone. In these settings, serological investigations are of great value in differential diagnosis.

Laboratory Findings

Aspergillus skin test: An immediate cutaneous hypersensitivity to *A. fumigatus* antigens is a hallmark of ABPA. The test can be performed using either a Skin Prick Test (SPT) or by intradermal injection of the antigen. A positive reaction is characterized by the development of a wheal and erythema within one minute, which reaches a maximum after 10 to 20 minutes, and resolves within 1 to 2 hours. A positive test result is found in virtually all patients with ABPA. However, almost 40% of asthmatic patients without ABPA can also demonstrate immediate skin reactivity to *Aspergillus* antigen.[91] Although theoretically both the intradermal and SPTs should perform in a similar manner, it has been shown that intradermal tests are generally more sensitive than SPTs.[92,93] The higher prevalence of AH with intradermal testing compared to prick test has been previously described in patients with ABPA.[92] In a meta-analysis we had observed that the prevalence of AH in bronchial asthma was higher with an intradermal test versus SPT (28.7% vs 24.8%). The intradermal test is also believed to be associated with a higher complication rate than SPT. However, in our experience of more than 5,000 intradermal tests, we have not encountered any complication.[4-7,23,44,94] Thus, if technically feasible, a prick test should be performed for *Aspergillus* skin testing, and if the prick test is negative it should be confirmed by an intradermal test.

Total serum IgE levels: The total IgE level is the most useful test for diagnosis and follow-up of ABPA. A normal serum IgE level excludes ABPA as the cause of patient's current symptoms, if the patient is not taking glucocorticoids. There is a controversy on what should be the cut-off value of IgE level that should be used for the diagnosis of ABPA. One Kilo Unit (KU) of IgE per liter is equivalent to one IU per milliliter and in turn is equal to 2.42 nanograms per milliliter.[95,96] Most studies have used a cut-off value of 1000 International Units (IUs) per milliliter,[5,6,16,17,97-100] but some authors use a cut-off value of 500 IU per milliliter.[2,37,40,41] We believe that a cut-off of 500 IU per milliliter will lead to overdiagnosis of ABPA as these levels are often seen in patients with AH without ABPA. As this will lead to unwarranted steroid therapy, hence we use a cut-off value of 1000 IU per milliliter. After treatment with glucocorticoids, the serum IgE level starts declining, but in most patients the level does not reach normal value. A 25 to 35% decline in IgE levels is taken as criteria for remission.[7,101] Repeated measurements of IgE levels need to be performed to determine the "new" baseline value for an individual patient during remission. The serum IgE also represents an important clinical tool in the follow-up of patients. A doubling of the patient's baseline IgE level signifies relapse of the disease.

Serum IgE and IgG antibodies specific to A. fumigatus: An elevated level of specific antibodies to *A. fumigatus* is considered the hallmark of disease and is measured by fluorescent enzyme immunoassay tests.[5] A cut-off value of IgG/IgE more than twice the pooled serum samples from patients with *Aspergillus*-hypersensitive asthma can help in the diagnosis of ABPA from patients with asthma and AH.[97] We currently use a cut-off of 0.35 kUA per liter of *A. fumigatus* specific IgE for the diagnosis of ABPA [the mean plus two standard deviation values of *A. fumigatus* specific IgE level of 25 patients with AH and asthma was found to be 0.245 kUA per liter using the fluorescent enzyme immunoassay (UniCAP Systems; Pharmacia and Upjohn Diagnostics; Stockholm, Sweden).]

Radiological investigations: A wide spectrum of radiographic abnormalities is encountered in ABPA (Table 75.5). The chest radiographic findings of ABPA include transient or fixed pulmonary opacities, which are often described as consolidation (Fig. 75.1).[102,103] Other findings include the presence of tramline shadows, finger-in-glove opacities and toothpaste shadows.[103-105] All these findings are due to mucus impaction of the bronchiectatic cavities.[106] On follow-up of these patients, there can be fibrosis and collapse mainly affecting the upper lobes[106] although there are no unique

TABLE 75.5: Radiologic findings (in order of frequency) encountered in patients with allergic bronchopulmonary aspergillosis

Chest radiographic findings

Patchy areas of consolidation, radiologic infiltrates – "toothpaste" and "gloved finger" shadows due to mucoid impaction in dilated bronchi, collapse - lobar or segmental, parallel-line shadows representing bronchial widening, ring-shadows representing dilated bronchi en face, fibrotic scarred upper lobes with cavitation, bronchial wall thickening – "tramline" shadows, air-fluid levels from dilated central bronchi filled with fluid, perihilar infiltrates simulating adenopathy, massive consolidation—unilateral or bilateral, small nodules, pleural effusions, pleural thickening.

High-resolution computed tomographic findings

Central bronchiectasis, mucus plugging with bronchoceles, consolidation, centrilobular nodules with tree-in-bud opacities, bronchial wall thickening, areas of atelectasis, mosaic perfusion with air-trapping on expiration, high-attenuation mucus (finding most helpful in differential diagnosis), pleural involvement, randomly scattered nodular opacities.

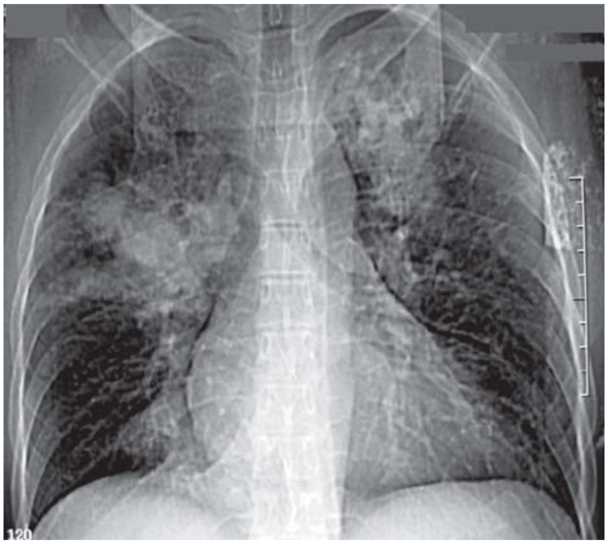

Fig. 75.1: Chest radiograph showing multifocal areas of consolidation

roentgenographic findings to define a particular stage.[107] Central bronchiectasis with peripheral tapering of bronchi is believed to be a sine qua non for the diagnosis of ABPA.[108] However, almost 40% of the bronchiectatic segments also have associated peripheral bronchiectasis.[5] Patients with ABPA who have CB are classified as ABPA-CB and those who meet all other criteria, but do not have central bronchiectasis are labeled as serologic ABPA (ABPA-S). The prevalence of CB in ABPA ranges from 69 to 76% in different studies (Table 75.4). High Resolution Computed Tomography (HRCT) has replaced bronchography as the imaging modality of choice for the diagnosis of bronchiectasis.[109] Findings on HRCT include the presence of central bronchiectasis, mucoid impaction, mosaic attenuation, presence of centrilobular nodules and tree-in-bud opacities (Fig. 75.2).[110,111] Mucoid impaction in ABPA can be of normal density or high density.[6] High-attenuation mucoid impaction, which is mucus visually denser than the paraspinal skeletal muscle, is a pathognomonic finding encountered in patients with ABPA (Fig. 75.3).[6,112-118] Although minimal bronchiectasis can be seen on HRCT in patients with bronchial asthma,[119,120] the findings of bronchiectasis affecting three or more lobes, centrilobular nodules and mucoid impaction are findings that are highly suggestive of ABPA.[121] The uncommon radiologic manifestations include miliary nodular opacities,[122] perihilar opacities simulating hilar lymphadenopathy,[88,103,123] pleural effusions,[124-126] pulmonary masses[127-132] and whole lung collapse.[133]

Serum precipitins against A. fumigatus: The precipitating IgG antibodies are elicited from crude extracts of *A. fumigatus* and other fungi and can be demonstrated using Ouchterlony double gel diffusion techniques of Longbottom and Pepys.[134] Present in almost 85% of the patients with ABPA, they probably indicate the continued growth of fungus in bronchi or body tissues.[135] These precipitins are however not specific as they are also present in 1 to 10% of normal subjects, hospitalized patients and other pulmonary disorders; and thus represent supportive, not diagnostic evidence for ABPA.[134-136]

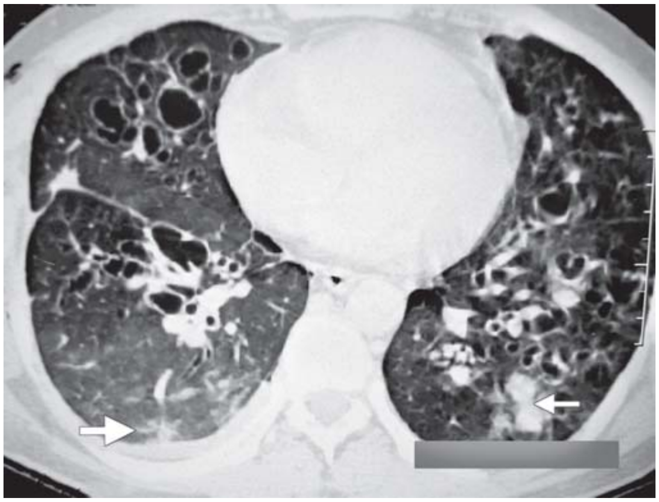

Fig. 75.2: High resolution computed tomographic image of a patient with allergic bronchopulmonary aspergillosis showing bilateral central bronchiectasis with centrilobular nodules (bold arrow) and mucus plugging (thin arrow)

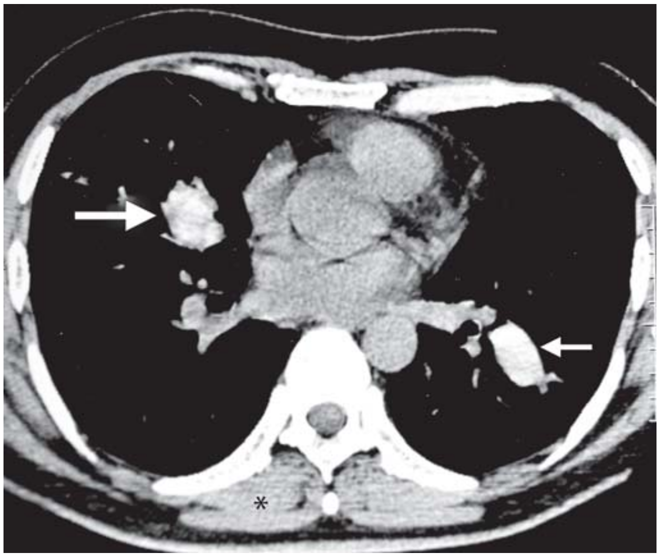

Fig. 75.3: Computed tomographic image of high-attenuation mucoid impaction (bold arrows). The mucoid impaction is visually denser than the paraspinal skeletal muscle (asterisk)

Peripheral eosinophilia: A blood absolute eosinophil count greater than 1000 cells per microliter is also taken as a major criterion for the diagnosis of ABPA. However, 53% of patients in one series[5] had an absolute eosinophil count less than 1000 cells per microliter and thus a low eosinophil count does not exclude the diagnosis of ABPA.

Sputum cultures for A. fumigatus: Culture of *A. fumigatus* in the sputum is supportive, but not diagnostic of ABPA. The fungus can also be grown in patients with other pulmonary diseases due to ubiquitous nature of the fungi. We do not perform sputum cultures for the diagnosis of ABPA.

Pulmonary function tests: These tests have no diagnostic value in ABPA, but help in categorizing the severity of asthma and/or the underlying lung disease. Bronchial challenge with *Aspergillus* antigens have been used in the past, but are not recommended as they can lead to acute bronchospasm, which can be fatal.[137] The pulmonary function tests generally show obstructive physiology with varying severity and reduction in diffusion capacity.[89,90,138] Pulmonary function tests can be normal in ABPA, and need not constitute the basis for screening.[5] Hence, it is recommended that all patients with bronchial asthma should be screened routinely for ABPA whatever the clinical severity or the lung function in physiological laboratories.[2,19,21,37,135-137,139-150]

Role of specific aspergillus antigens: Patients with ABPA are mostly evaluated with crude extracts from *Aspergillus.* These antigens lack reproducibility and consistency and frequently cross react with other antigens.[151] Advances in molecular techniques have enabled detection of almost 20 specific *Aspergillus* antigens with diverse biochemical nature and function. In fact, a number of allergens from *A. fumigatus* have been cloned. A number of these antigens have also been evaluated for the diagnosis of ABPA both in patients with asthma and cystic fibrosis. The recombinant allergens Asp f1, Asp f2, Asp f3, Asp f4 and Asp f6 have been evaluated for their diagnostic performance in serological studies in asthmatic patients[152-155] and in patients with CF.[154,156-158] Preliminary data suggest a promising role of these antigens in the diagnosis of ABPA. Further studies are required before they can be implemented in routine clinical practice.

Diagnosis and Diagnostic Criteria

The Rosenberg-Patterson criteria are most often used for the diagnosis (Table 75.6). The criteria continue to be challenged and modified.[3] The presence of six out of eight major Rosenberg criteria makes the diagnosis almost certain. There are also a set of minimal diagnostic criteria for ABPA using which the diagnosis of ABPA may be secured, possibly at an earlier stage.[40,159] The differentiation of patients with ABPA from patients with AH can also be problematic. Serum precipitins to *A. fumigatus* is present in 69 to 90% of patients with ABPA,[6,89,134,160,161] but also in 9% of asthmatics.[134] Central bronchiectasis can be seen in patients with asthma without ABPA.[119-121] The total IgE levels are elevated in the sera in all patients with ABPA, and reflect disease activity,[162,163] however, a moderate rise in IgE levels is also noted in patients with asthma without ABPA.[164] The use of IgE and IgG levels specific to *A. fumigatus* can help in diagnosis as they are significantly raised only in patients with ABPA when compared to asthmatic patients. In fact, values of IgG/IgE more than twice the pooled serum samples from patients with asthma who have AH can greatly help in diagnosis of ABPA.[135,165] We have recently proposed new criteria to simplify the diagnosis of ABPA (Table 75.6).

While investigating a patient with asthma, we first perform an *Aspergillus* skin test. Once it is positive, the total serum IgE levels are done. If the value is more than 1000 IU per milliliter, we perform the other tests, which include a HRCT of the chest, IgE and IgG specific to *A. fumigatus*, absolute eosinophil count and serum

TABLE 75.6: Criteria used for the diagnosis of allergic bronchopulmonary aspergillosis

Rosenberg-Patterson criteria[14,17]

Major criteria

- Bronchial asthma
- Immediate cutaneous hyperreactivity to *Aspergillus* antigen
- Elevated serum IgE levels (>1000 IU/mL)
- Elevated levels of *A. fumigatus*-specific IgG and/or IgE in serum
- Central bronchiectasis
- Fleeting pulmonary opacities on chest radiograph
- Peripheral eosinophilia (>1000/μL)
- Elevated serum precipitins against *Aspergillus*
- Precipitating antibodies (IgG) in serum

Minor criteria

- Expectoration of brownish-black mucus plugs
- Delayed cutaneous hypersensitivity to *Aspergillus* antigen
- Presence of *Aspergillus* in sputum
- The presence of six out eight major criteria makes the diagnosis almost certain. The disease is further classified as ABPA-S or ABPA- CB on the absence or presence of CB respectively

Agarwal criteria for allergic bronchopulmonary aspergillosis[94]

Predisposing conditions

- Bronchial asthma
- Cystic fibrosis
- Chronic obstructive pulmonary disease
- Others (hyper-IgE syndrome, chronic granulomatous disease, Kartagener's syndrome)

Obligatory criteria

- Elevated total IgE levels (more than 1000 IU per milliliter)
- Elevated IgE and/or IgG levels against *A. fumigatus*

Other criteria (at least three of five)

- Immediate cutaneous hypersensitivity to *Aspergillus* antigen
- Presence of serum precipitating antibodies against *A. fumigatus*
- Radiographic pulmonary opacities (fixed/transient)
- Absolute eosinophil count more than 1000 cells per microliter
- Central bronchiectasis on HRCT

precipitins to *A. fumigatus*. If the value is between 500 and 1000 IU per milliliter, the next step is analysis of *A. fumigatus* specific IgE and IgG antibodies. If the levels are raised, the patient is followed every six weeks with total IgE levels. If the absolute value rises above 1000 IU per milliliter or there is a rising trend with clinical/ radiologic deterioration, the treatment is started. If the value is between 500 and 1000 IU per milliliter and IgE and IgG specific to A. fumigatus are not raised, the patient is followed up with a yearly total IgE levels.[94]

Natural History

The natural history of ABPA is currently not well characterized and is often difficult to predict because spontaneous improvement of symptoms and pulmonary opacities characterize an important aspect of the disease.[17,98,166-169] ABPA is most often a non-acute respiratory syndrome that lingers on for years without diagnosis. Rarely, the condition presents in an acute fashion.[133, 170, 171] However, if the disease is not recognized, the chronic inflammatory process can progress inexorably and result in irreversible pulmonary dysfunction due to bronchiectasis and/or pulmonary fibrosis, and ultimately respiratory failure and cor pulmonale.[20] Thus, an early diagnosis and initiation of systemic corticosteroids are essential for the treatment of ABPA to prevent bronchiectasis and/or pulmonary fibrosis.[172] The natural history of ABPA is characterized by recurrent episodes of remissions and relapses. It can be best understood if we understand the clinical and radiological classification schemes of ABPA (Table 75.7).

Clinical staging of ABPA: Although ABPA has been classified into five stages a patient does not necessarily progress from one stage to the other in a sequential fashion (Table 75.7). Patients who present with acute to subacute symptoms are generally in **stage I or III** depending on whether or not the disorder has been previously diagnosed. The patient usually presents with radiographic infiltrates, elevated IgE (generally between 5500-7500 IU per milliliter) and *A. fumigatus*-specific IgG/ IgE levels.[6] There is clearing of radiographic opacities in most patients with 25 to 40% decline in IgE levels by six weeks after the institution of glucocorticoids.[7] By the end of three months almost all patients show at least 50% decline in the total IgE levels and the patient is said to be in remission or in **stage II**. Almost 50% of the patients have relapse/exacerbation of the disease (**stage III**), which is defined as doubling of the baseline IgE levels usually with worsening of patient's symptoms or the appearance of radiologic infiltrates.[5,16,17] If the patient does not have any additional ABPA exacerbations over the next three months after stopping therapy, we give an additional label of "complete remission." Patients who are in complete remission are followed up by measuring IgE levels every six months for the first year and then annually, modified depending on the clinical status of the patient. Even in patients who have achieved complete remission, the IgE levels do not return to normal values.[166] This is an important point because the aim of glucocorticoid therapy is not the achievement of normal IgE levels, but a 25 to 50% decline by six weeks to three months.[101] Some patients in stage III may enter into prolonged or even a permanent remission. A complete remission, however, does not imply a permanent remission as exacerbations of the disease have been documented for as long as seven years after remission.[168]

TABLE 75.7: Classification of allergic bronchopulmonary aspergillosis

Clinical classification of ABPA[5,16]	
Patterson stage	
I	Acute phase
II	Remission
III	Exacerbation
IV	Glucocorticoid-dependent ABPA
V	End-stage (Fibrotic) ABPA
Radiologic classification of ABPA[20,174]	
Greenberger classification	
Seropositive ABPA (ABPA-S)	All the diagnostic features of ABPA, but no evidence of central bronchiectasis on HRCT. Patients with ABPA-S may be classified as Patterson stages I to IV. These patients may have recurrent exacerbations and may also be classified as stage III
ABPA with central bronchiectasis (ABPA-CB)	All findings of ABPA, including CB on HRCT. Patients with ABPA-CB may belong to any of the Patterson stages
Kumar classification	
ABPA-S	ABPA without CB
ABPA-CB	ABPA with CB
ABPA-CB-other radiologic findings (ABPA-CB-ORF)	ABPA with CB other radiologic features, such as pulmonary fibrosis, bleb, bullae, pneumothorax, parenchymal scarring, emphysematous change, multiple cyst, fibrocavitary lesions, aspergilloma, ground-glass appearance, collapse, mediastinal lymph node, pleural effusion and pleural thickening
Agarwal classification (submitted for publication)	
ABPA-S	ABPA without CB
ABPA-CB	ABPA with CB
ABPA-CB-high attenuation mucus (ABPA-CB-HAM)	ABPA with CB and high attenuation mucus

Patients in **stage IV** (glucocorticoid-dependent disease) are of two types. The first group (glucocorticoid-dependent asthma) includes patients who require oral glucocorticoids for the treatment of persistent asthma, but in whom the IgE levels do not vary significantly overtime. In the other group of patients (glucocorticoid-dependent ABPA), the IgE levels rise once the steroids are tapered and continuous glucocorticoid therapy is required for the control of ABPA.[5,18] Patients in **stage V** are those with widespread bronchiectasis and varying degrees of pulmonary dysfunction on lung function tests although there are no specific criteria for the classification of this stage. We currently define patients in stage V only if they have type II respiratory failure and/or cor pulmonale. It is important to remember that the IgE level declines to below 1000 IU per milliliter in only a minority of patients with stages II and V (less than 10 to 15% of stages II and V).[98,166] Even in stage V ABPA, the disease can be clinically as well as immunologically active, and long-term glucocorticoid therapy may be required for the control of asthma and/or ABPA.[169,173]

Radiological classification of ABPA: ABPA is also classified as ABPA-S or ABPA-CB respectively depending on the absence or presence of bronchiectasis (Table 75.7). Patients with ABPA-S probably represent the earliest stage of the disorder. It is also believed that patients with ABPA-S have a milder clinical course and less severe immunologic findings when compared to ABPA-CB.[20,174,175] In the largest of these three studies (76 patients), which was also the first study which suggested that ABPA-S is less severe immunologically, only the *A. fumigatus*-specific IgG levels were higher in patients with ABPA-CB compared to ABPA-S. Other immunologic parameters were not significantly different between the two groups.[20] One author has also classified the disease into three groups; ABPA-S (mild), ABPA-CB (moderate) and ABPA-CB-Other Radiologic Findings (ORFs). However, this was a single study and included only 18 patients.[174] Also, the findings included in the categorization of ABPA-CB-ORF were pulmonary fibrosis, bleb, bullae, pneumothorax, parenchymal scarring, emphysematous change, multiple cyst, fibrocavitary lesions and pleural thickening; which are all changes representing the fibrotic stage of the disease. In ABPA-S there is active ongoing inflammation with progressive immunologic damage, and understandably the immunologic findings will not be very different from those in ABPA-CB. Recently, we have re-evaluated the clinical and serological severity of both these classifications using data from a large set of patients and propose a new classification scheme based on High-Attenuation Mucus (HAM) (unpublished data). The classification scheme by Greenberg et al. showed immunological severity in some parameters (eosinophil count and *A. fumigatus*-specific IgE levels), but not in others (total IgE levels). Moreover, on excluding patients with HAM, the immunological severity was restricted only to eosinophil counts. Interestingly, in the Kumar classification, the immunological markers were most severe in patients with ABPA-CB and not ABPA-CB-ORF. This suggests that ORF does not determine serological severity and probably represents the burnt out phase of the disease. The HAM classification was most consistent with the immunological severity persisting even after removal of patients (Table 75.7). Based on the results of this study, we believe that ABPA should be classified as ABPA-S, ABPA-CB and ABPA-CB-HAM because this classification not only suggests immunological severity, but also predicts patients who are likely to have frequent relapses.

The course of patients with ABPA-S is likely to be less severe when compared to those with ABPA-CB. In two separate multivariate analyses of 155 and 54 patients with ABPA, we demonstrated that the severity of bronchiectasis and presence of hyperattenuating mucoid impaction on HRCT predicted relapses of ABPA and the severity of bronchiectasis was an independent predictor of failure to achieve long-term remission.[6,7] This is an important observation and suggests that an early diagnosis of ABPA is essential because one not only prevents permanent lung damage, but also improves the likelihood of a smoother course of this relapsing-remitting disorder. Thus, it remains prudent to diagnose and treat ABPA early so as to prevent the development of bronchiectasis.

Management

The management of ABPA includes two important aspects: Institution of immunosuppressive therapy, primarily glucocorticoids to control the immunologic activity, and close monitoring for the detection of relapses. Another possible target is to use antifungal agents to attenuate the fungal burden secondary to the fungal colonization in the airways.

TABLE 75.8: Glucocorticoid protocols for the management of ABPA

Regime 1[2]
Prednisolone 0.5 mg/kg/day for one to two weeks, then on alternate days for six to eight weeks. Then taper by 5-10 mg every 2 weeks and discontinue. Repeat total serum IgE levels and chest X-ray every six to eight weeks to determine the baseline IgE concentrations.

Regime 2[5,135]
Prednisolone, 0.75 mg/kg for 6 weeks, 0.5 mg/kg for 6 weeks, then tapered by 5 mg every 6 weeks to continue for a total duration of at least 6 to 12 months. The total IgE levels are repeated every six to eight weeks for one year to determine the baseline IgE concentrations.

Systemic glucocorticoid therapy: Oral corticosteroids are the treatment of choice for ABPA. They not only suppress the immune hyperfunction, but are also anti-inflammatory. However, different regimens of glucocorticoids have been used as there is no robust data to guide the dose and duration of glucocorticoids (Table 75.8). The use of lower doses of glucocorticoids (regime 1 in Table 75.8) is associated with frequent relapses or corticosteroid dependence (45%).[17] We use a higher dosage of glucocorticoids for a longer duration (regime 2 in Table 75.8), and observed a higher remission rates and a lower prevalence of glucocorticoid-dependent ABPA (13.5%).[5] This raises the possibility of a higher dose and prolonged duration of corticosteroid therapy being associated with better outcomes. However, there are no direct comparisons between the two regimens and the selection is a matter of personal preference. Currently, a randomized controlled trial is underway to assess the efficacy of two different glucocorticoid regimens in ABPA.

The clinical effectiveness of steroid therapy is reflected by decrease in the patient's total serum IgE levels (there seems to be no correlation between serum levels of *A. fumigatus*-specific IgE levels and disease activity[176]) along with symptom and radiographic improvements. The goal of therapy is not to attempt normalization of IgE levels, but to decrease the IgE levels by 25 to 50%, which in most cases leads to clinical and radiographic improvement. One should also aim to establish a stable baseline serum level of total IgE, which serves as a guide to future detection of relapse and helps in follow-up of the patient.

Inhaled corticosteroids: Although small case studies suggest some benefit of inhaled corticosteroids in management of ABPA,[177-180] a double blind multicenter placebo controlled trial in 32 patients suggested no superiority over placebo.[181] Currently, there is no role of inhaled corticosteroids in the management of ABPA. We use inhaled corticosteroids only for the control of asthma, once the oral prednisolone dose is reduced to below 10 milligrams per day.

Oral itraconazole: The use of specific antifungal agents in ABPA has the advantage of modifying the immune response by removing/reducing the antigenic stimulus consequent to a decreased fungal burden. Ketoconazole has been tried in the past[182] and has been replaced by the less toxic agent, itraconazole.[100,176,183-195] However, only two randomized controlled studies (84 patients) have evaluated the role of itraconazole in ABPA.[100,191] In one study, 55 patients with "glucocorticoid-dependent" ABPA were randomized to receive either itraconazole 200 milligrams twice a day versus placebo. While the difference between the two groups was significant in the terms of overall response [reduction in the dose of corticosteroid by 50% or more; and decrease in the total IgE concentration by 25% or more; and at least one of the following (increase in exercise tolerance by at least 25%, improvement by 25% in results of the pulmonary function tests, resolution of pulmonary infiltrates)], but failed to reach statistical significance when each of the outcomes were examined separately.[191] The other study included 29 "clinically stable" ABPA patients randomized to receive itraconazole or placebo. Interestingly, majority of the patients did not receive glucocorticoids. There were significant decline in sputum inflammatory markers and serum IgE levels. The study also demonstrated a decrease in the number of exacerbations warranting glucocorticoid usage.[100] Pooled analysis showed that itraconazole could significantly decrease the IgE levels by 25% or more when compared to placebo, but did not cause significant improvement in lung function.[196] A major limitation was that neither of the study reported long-term outcomes in the terms of relapses of ABPA. Thus, long-term trials are required before a firm recommendation can be made for the use of itraconazole as adjunctive treatment for patients with ABPA. We currently use itraconazole only after the first relapse of ABPA despite glucocorticoid therapy or in patients with glucocorticoid-dependent ABPA. In the limited numbers of patients in whom we have used the drug, there was no observable advantage.[5]

Itraconazole also has numerous adverse effects. In a study of 189 patients treated with itraconazole (average, 400 milligrams per day), adverse effects occurred in almost 39% of patients.[197] There are also numerous drug interactions with the use of itraconazole. Most notably it may inhibit the hepatic metabolism of terfenadine, astemizole and cisapride, prolonging the electrocardiographic QT interval thus increasing the risk for cardiac arrhythmia. Caution should also be exercised when treating concomitantly with glucocorticoids. Itraconazole inhibits the metabolism of methylprednisolone (but not prednisolone) and can lead to the increased frequency of side-effects of steroids, including profound adrenal insufficiency.[198]Adrenal suppression has also been reported with the concomitant use of itraconazole and inhaled budesonide.[199,200]

Other Therapies: Numerous other therapies have been tried in ABPA. They can be tried in an individual patient, but should not be used as a routine measure. There is a single patient case report of ABPA treated with inhaled amphotericin and budesonide.[201] Similarly, there are numerous case records on the use of omalizumab for the management of ABPA.[171,202-207] Pulse doses of intravenous methylprednisolone have also been used in the treatment of severe ABPA.[170,171,208,209] Recently, voriconazole has also been tried in the treatment of ABPA.[210-213] We also use methotrexate as steroid-sparing agent in patients with steroid-dependent ABPA or in patients where steroids are absolutely contraindicated, such as cystoid macular edema, which is a potentially sight-threatening condition.

Differential Diagnosis

The diagnosis of the condition rests on clinical suspicion and performance of serological and radiological tests, including HRCT of the chest. Occasionally, the disorder needs to be differentiated from the following conditions: Pulmonary tuberculosis in endemic areas, community-acquired pneumonia (especially acute presentations of ABPA), and other inflammatory pulmonary disorders such as eosinophilic pneumonia, bronchocentric granulomatosis and Churg-Strauss syndrome.

Complications

The complications of ABPA include recurrent asthma exacerbations, and if untreated it leads to the development of bronchiectasis with the occurrence of pulmonary hypertension and type 2 respiratory failure. We have also encountered a patient who has developed secondary amyloidosis due to the bronchiectasis associated with ABPA. In fact, this is the reason why routine screening is recommended in bronchial asthma to prevent the aforementioned complications.

ABPA without Bronchial Asthma

ABPA is most commonly known to complicate the course of pre-existing bronchial asthma. However, ABPA may occasionally develop in an individual without pre-existing bronchial asthma. In a systematic review for the occurrence of ABPA without bronchial asthma, we found 36 cases reported across the globe.[122] Two cases demonstrated bronchodilator reversibility,[214] and one showed airway hyperresponsiveness to methacholine challenge.[215] Majority of the cases demonstrated hypersensitivity to *A. fumigatus*, but three cases showed hypersensitivity to *Helminthosporium*,[214] and one case each to *A. niger*.[216,217] Because of the absence of bronchial asthma, these cases are often mistaken initially for other pulmonary disorders like bronchogenic carcinoma [217-219] or pulmonary tuberculosis.

ABPA in Cystic Fibrosis

The association of ABPA and CF was first reported in 1965 by Mearns et al who reported two cases of ABPA in CF.[220] ABPA is now recognized as a potential complication in patients with CF.[221] The pathogenesis is similar to that of bronchial asthma, and a key element in the immunopathogenesis may be exposure of the bronchial lymphoid tissue to high levels of *Aspergillus* allergens, perhaps because of abnormal mucus properties resulting from the CF transmembrane conductance regulator mutations.[222] Unlike asthma, the recognition of ABPA in CF is difficult as ABPA shares many clinical characteristics with poorly controlled CF lung disease. Presence of wheezing (due to intercurrent infections), transient pulmonary infiltrates, bronchiectasis and mucus plugging are common manifestations of CF-related pulmonary disease with or without ABPA.

Numerous studies have described the prevalence of AH and/or ABPA in patients with CF.[188,223-249] A meta-analysis of these studies suggest the prevalence of AH in CF of 34% (95% CI, 27 to 41) and the prevalence of ABPA of 7.8% (95% CI, 5.8 to 10).[1] There was however, no uniformity in the diagnostic criteria with varying criteria used for the diagnosis of AH and ABPA in different studies. This fact was also reported in a questionnaire-based study, which revealed a considerable variability in the criteria used for the diagnosis of ABPA in CF.[250] Therefore, prospective reporting of cases with uniform criteria would be the only way to reliably identify the true prevalence of ABPA in CF, and it is likely that database surveys may have overestimated the true prevalence. Atopy seems to be an important risk factor for ABPA in CF. In cystic fibrosis, ABPA was seen in 22% of atopic patients and only 2% of nonatopic patients.[188,238,240,245]

Although, a number of patients with CF develop sensitization to *A. fumigatus* with an increase in total and *A. fumigatus*-specific IgE levels; the surprising aspect is that many a patient demonstrate a spontaneous decrease in many immunologic parameters, including IgE levels.[234] Thus, the diagnosis of ABPA in CF should not be based solely on serology and skin test results as patients with CF may demonstrate variable responses to *A. fumigatus* and prolonged testing might be required to make a definite diagnosis (Table 75.9). It is important to identify the development of ABPA in patients with CF as it has been shown that the deterioration of lung function is most strikingly pronounced in patients with ABPA compared with a control group of CF patients not sensitized to *A. fumigatus*.[188,247,251] Also patients with ABPA and CF were demonstrated to have higher rates of microbial colonization, pneumothorax, massive hemoptysis and poorer nutritional status.[242]

The treatment of ABPA in CF is not very different from that of ABPA in bronchial asthma except the fact that there is minimal data to formulate conclusive treatment recommendations for ABPA in CF. The treatment issues are further complicated by the fact that pulmonary exacerbations in a patient with ABPA and CF could be related to ABPA, pulmonary infection, and hence continuous assessment may be required over months with repeat performance of all the serological investigations for ABPA before a decision to treat an individual case is made.[221]

Coexistence of ABPA and Aspergilloma

The serological findings of ABPA has also been reported in patients with aspergilloma[252-262] and chronic necrotizing pulmonary aspergillosis.[263] This ABPA-like syndrome can be true hypersensitivity reaction consequent to the colonization of *Aspergillus* in long-standing pulmonary cavities of pulmonary diseases like tuberculosis or sarcoidosis.[252,253] Probably there is a continuous release of *Aspergillus* antigens, which leads to immunologic activation in a genetically predisposed

TABLE 75.9: Consensus conference proposed diagnostic and screening criteria for ABPA in CF[221]

Classic diagnostic criteria

1. Acute or subacute clinical deterioration (cough, wheeze and other pulmonary symptoms) not explained by another etiology
2. Serum total IgE levels >1000 IU/mL
3. Immediate cutaneous reactivity to *Aspergillus* or presence of serum IgE antibody to *A. fumigatus*
4. Precipitating antibodies to *A. fumigatus* or serum IgG antibody to *A. fumigatus*
5. New or recent abnormalities on chest radiography or chest CT that have not cleared with antibiotics and standard physiotherapy

Minimal diagnostic criteria

1. Acute or subacute clinical deterioration (cough, wheeze and other pulmonary symptoms) not explained by another etiology
2. Total serum IgE levels >500 IU/mL. If total IgE level is 200-500 IU/mL, repeat testing in 1-3 months is recommended
3. Immediate cutaneous reactivity to *Aspergillus* or presence of serum IgE antibody to *A. fumigatus*
4. One of the following: (a) precipitins to *A. fumigatus* or demonstration of IgG antibody to *A. fumigatus*; or (b) new or recent abnormalities on chest radiography (on chest radiography or chest CT that have not cleared with antibiotics and standard physiotherapy

Screening for ABPA in CF

1. Maintain a high level of suspicion for ABPA in patients with CF
2. Determine the total serum IgE levels annually. If the total serum IgE levels is >500 IU/mL perform *A. fumigatus* skin test or use an IgE antibody to *A. fumigatus*. If results are positive, consider diagnosis on the basis of minimal criteria
3. If the total serum IgE levels is 200-500 IU/mL, repeat the measurement if there is increased suspicion for ABPA and perform further diagnostic tests (immediate skin test reactivity to *A. fumigatus*, IgE antibody to *A. fumigatus*, *A. fumigatus* precipitins, or serum IgG antibody to *A. fumigatus* and chest radiography)

individual, thus leading to serological manifestations of ABPA. On the other hand, it can also represent saprophytic *Aspergillus* colonization and subsequent aspergilloma formation in bronchiectatic cavities of ABPA.[261,262] Whatever, the predisposing causes, most patients show brisk response to glucocorticoids.[252-255,262]

Allergic Bronchopulmonary Mycosis

Allergic bronchopulmonary mycosis is the occurrence of ABPA-like syndrome due to non-*Aspergillus fumigatus* fungal organisms. A variety of fungal agents (Table 75.10) have been reported to cause this syndrome, but the frequency is far less when compared to ABPA.[256,264-278]

ABPA Complicating Other Conditions

ABPA is mainly described in patients with bronchial asthma or cystic fibrosis. Occasionally, ABPA has been reported to complicate other lung diseases like idiopathic bronchiectasis,[279] post-tubercular bronchiectasis,[280] bronchiectasis secondary to Kartagener's syndrome,[281] chronic obstructive pulmonary disease,[94,282] and in patients with chronic granulomatous disease and hyper IgE syndrome.[283] However, these are single patient case reports or small case studies, and larger observations are required to definitely establish an association.

TABLE 75.10: Fungi implicated in the causation of allergic bronchopulmonary mycosis

Aspergillus niger[256]
Helminthosporium spp[264]
Penicillium spp[265]
Aspergillus ochraceus[266]
Stemphylium spp[267]
Aspergillus terreus[268]
Drechslera spp[269]
Torulopsis spp[270]
Mucor-like spp[271]
Candida spp[272]
Pseudallescheria spp[273]
Bipolaris spp[274]
Curvularia spp[274]
Schizophyllum spp[275]
Fusarium spp[276]
Cladosporium spp [277]
Saccharomyces spp [278]

Sinobronchial Allergic Mycosis (SAM) Syndrome

The presence of concomitant allergic fungal sinusitis and ABPM in the same patient represents an expression of the same process of fungal hypersensitivity involving the upper and lower airways and is called the SAM syndrome.[35] Allergic *Aspergillus* Sinusitis (AAS), is an entity in which mucoid impaction similar to that of ABPA occurs in the paranasal sinuses.[284] The pathogenesis is similar to ABPA and represents an allergic hypersensitivity response to the presence of fungi within the sinus cavity.[285] It can also be regarded as the upper airway analog of ABPA. The patient can be asymptomatic or manifest with symptoms of nasal obstruction, rhinorrhea, headache and epistaxis. In clinical practice, it may not be possible to confirm the diagnosis of AAS in many patients as they decline to undergo the procedures required to establish the diagnosis. We currently label patients with ABPA as having concomitant AAS if there is a combination of hyperattenuating mucus and/or bony erosion on a paranasal CT scan. Treatment is initiated for ABPA with patients receiving additional intranasal glucocorticoids. If the symptoms persist or are troublesome, surgical management may be required for the management of AAS.

Occasionally, the inflammatory mass (fungocele) from the sinus may extend into adjacent spaces, such as orbit and manifest as proptosis.[286] Some patients can also have an intracranial extradural spread. Histopathological examination can show findings of branching septate fungi interspersed with eosinophilic mucin and Charcot-Leyden crystals without the fungal invasion of soft tissue, with intracranial extension.[287] It is important to differentiate this entity from invasive rhinocerebral aspergillosis as many patients are inadvertently treated with intravenous amphotericin when in fact they should be treated with minimally invasive surgery and glucocorticoid therapy (with or without concomitant azole therapy).[287]

CONCLUSION

A high index of suspicion for ABPA should be maintained while managing any patient with bronchial asthma whatever the severity or the level of control. Host immunologic responses are central to the pathogenesis and are the primary determinants of the clinical, biological, pathological and radiological features of this disorder. ABPA may precede the clinical recognition of the disorder for many years or even decades, and is often misdiagnosed for a variety of pulmonary diseases. As a patient with ABPA can be minimally symptomatic or asymptomatic, all patients with bronchial asthma should be routinely screened with an *Aspergillus* skin test. In patients with *Aspergillus* hypersensitivity further immunologic studies are warranted to diagnose ABPA before the development of bronchiectasis as bronchiectasis is a poor prognostic marker in the natural history of this disease.

Chronic Obstructive Pulmonary Disease: The Neglected Epidemic

Sundeep Salvi

MORTALITY DUE TO CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic Obstructive Pulmonary Disease (COPD) is a growing global epidemic that is estimated to kill around three million people every year. It is currently the fourth largest killer disease in the world and expected to climb to the third position by the year 2030. The numbers of deaths due to coronary heart disease, stroke and other cardiovascular diseases have reduced substantially over the years, whereas COPD is the only disease whose mortality rates have increased substantially. The WHO has estimated that mortality rates due to COPD will increase by around 160% in the Southeast Asian region over the next two decades. Half a million people are estimated to die due to COPD in India every year, the second largest number in the world after China. A recent report has indicated that COPD is already the leading cause of mortality in the state of Maharashtra and causes even more deaths than those due to coronary heart disease and stroke.

MORBIDITY DUE TO COPD

The World Health Organization (WHO) has estimated that 600 million people worldwide have COPD. It affects around 5% to 10% of the population over the age of 40 years, although there are wide variations in the prevalence between countries. Although a gross underestimate of the COPD prevalence in India has been estimated as 17 million and it is anticipated to increase by over 30% in the next decade. COPD is a common and leading cause of morbidity that is associated with the worsening of quality of life; 80% of patients hospitalized following an exacerbation report a health status rated by a physician as being worse than death. The patients who survive their first COPD-related hospitalization, up to 50% are reported to be readmitted within six months of discharge.

THE ECONOMIC BURDEN OF COPD

COPD is associated with a huge economic loss, not only for the patient but also for the nation. The economic burden of COPD is estimated as 38.8 billion US$ for US and 38.6 billion US$ for Europe. The estimated economic burden due to COPD for India is ` 30,000 crores (7.5 billion US$). Up to 84% of the direct costs associated with COPD are due to inpatient hospitalizations; lost productivity due to COPD accounts for between 40% and 67% of the overall costs across the world. COPD is, therefore, a major economic burden for countries throughout the world.

RISK FACTORS FOR COPD

Tobacco smoking is believed to be the biggest risk factor for COPD globally, accounting for between 80% to 85% of all COPD cases in the developed world. Tobacco smoking is steadily growing in most of the developing countries. In India and other Southeast Asian countries, bidi smoking is more popular than cigarette smoking mainly because of its low cost. In the bidi, tobacco is packed inside dried tendu leaves and although the amount of nicotine is about one-third to one-fourth the amount present in cigarettes, the amount of tar it produces is about five times more; therefore, from a COPD risk point of view, one bidi is as harmful as one cigarette. In India, other forms of tobacco smoking also exist, such as hookah and chillum. A recent study that compared the differences in lung oxidative stress mediated by different types of smoking devices showed that the hookah and chillum elicited greater amounts of lung oxidative stress than bidis and cigarettes, suggesting that hookahs and chillums are more harmful than bidis and cigarettes.

Recent emerging evidence suggests, if not more, that other nonsmoking risk factors may be equally important than tobacco smoking. It has been recently argued that exposure to biomass fuel smoke is perhaps the biggest risk factor for COPD globally. Compared to 1.1 billion smokers worldwide, three billion people (about half of the world's population) are exposed to the high levels of indoor air pollution due to the burning of biomass fuel smoke. Around 70% of homes in India are estimated to use biomass fuel for cooking and/or heating purposes, most of which are poorly ventilated. During her lifetime, every woman who spends two to three hours for cooking, every day inhales a volume of 25 million liters of highly polluted air, thereby exposing to her to extremely high levels of particulate matter and gaseous air pollutants. Exposure to biomass fuels has been shown to be as great a risk factor for COPD as active smoking and a greater threat than passive smoking, thus matching and beating two factors traditionally considered to be the major causes of COPD.

A previous history of pulmonary tuberculosis has been shown to be an independent and strong risk factor for the development of "obstructive airways disease," which is more of the COPD phenotype. In countries from Africa, Asia and Southeast Asia, where tuberculosis is highly prevalent, the burden of COPD due to a prior history of pulmonary tuberculosis is expected to be very high. In fact, a history of tuberculosis has been shown to be a bigger risk factor for COPD than tobacco smoking in studies from Africa and Asia.

Chronic poorly treated persistent asthma has also been identified as an important risk factor for COPD and its contribution to the overall prevalence of COPD is expected to be high in developing countries, where asthma still remains poorly diagnosed and treated. The other risk factors for COPD that have been identified are occupational causes, nutritional factors and poor socioeconomic status and these have been discussed in detail in the Chapter on "Risk Factors for COPD." Genetic factors have attracted more attention recently because of rapid advancements in the field of genomics. Alpha-1 antitrypsin deficiency remains one of the important genetic diseases associated with the development of COPD that roughly affects about 1% of the COPD population and it seems likely that more COPD genes will be identified in the near future.

As most clinicians from India and the Southeast Asia-Pacific region read textbooks of respiratory medicine authored by British and American authors, the concept of COPD in nonsmokers is not as much highlighted as it deserves. We almost take it for granted that if the patient who comes to the clinic with symptoms suggestive of COPD, but does not smoke, does not have COPD; because we have been lead to believe that COPD is almost always caused by tobacco smoking. This mind set now needs to change with the new evidence that almost half the COPD population in this part of the world occur due to nonsmoking causes.

COPD Remains Poorly Recognized

Despite such a huge and growing health and economic burden, COPD remains poorly recognized in clinical practice and underappreciated by health care providers, researchers and policy makers. One of the main reasons for this has been an "identity crisis" for this disease terminology. COPD has been previously known as "chronic bronchitis", "emphysema", "chronic obstructive lung disease", "chronic airflow limitation", "chronic obstructive respiratory disease", "chronic obstructive bronchopulmonary disease", "nonspecific chronic pulmonary disease", "diffuse obstructive pulmonary syndrome" and "chronic obstructive airways disease." These different names created a lot of confusion amongst clinicians and policy makers. Moreover, none of the terms were actually helpful in diagnosing the disease in clinical practice.

One of the other reasons why COPD as a disease remained unrecognized and unimportant was the attitude by the health care providers that this was a disease that was "self inflicted" because of its strong association with tobacco smoking. The patients were, therefore, thought to deserve the suffering brought about by their smoking habit. Moreover, there were no powerful medications that could bring about significant improvements in symptoms and prevent the rapid decline in lung function that accompanied the disease. There was no remarkable treatment that a physician could offer to patients suffering with COPD. As a result, the overall approach was very "nihilistic" towards this disease.

COPD Remains Underdiagnosed in Clinical Practice

COPD remains grossly underdiagnosed in clinical practice. This is mainly because of underuse of spirometry. Studies from US, UK and other European countries have indicated that if history and clinical examination are the only tools used to diagnose COPD in clinical practice, more than half of the COPD patients will remain underdiagnosed. Despite this realization, spirometry continues to be underused in clinics and even hospital settings. There are several reasons that have been suggested for this and include the lack of training during undergraduate and postgraduate medical curriculum about spirometry, the perception that spirometry is a difficult and time consuming test to perform and interpret, and the fact that spirometers are expensive (although this is no longer true since the cost of spirometers have come down dramatically over the years). Clinicians who are involved in managing patients with COPD should, therefore, be encouraged to use spirometry routinely, not only for arriving at a diagnosis, but also for evaluating the response to treatment.

More recently, the role of the Impulse Oscillometer (IOS) has attracted attention as a useful diagnostic tool for measuring airflow obstruction. This tool measures airflow resistance by passing in sound waves into the lungs at different frequencies and measuring the resistance offered for the passage of these sound waves. By using sound waves of different frequencies, we can measure the presence of airflow obstruction proximally as well as distally. The unique advantage of this instrument is that it measures these parameters during normal tidal breathing. This instrument is considerably more expensive than the spirometer as its use will continue to increase the prices are anticipated to go down.

Body box plethysmography and carbon monoxide lung diffusion studies help to measure the total lung capacity and the function of the lung alveolar-capillary diffusion apparatus. Although useful to diagnose emphysema, the degree of air trapping and the loss of alveolar surface area in COPD, they are not available even in some of the tertiary care specialist hospitals. These instruments are particularly helpful in determining surgical operability and estimating the potential benefit of Lung Volume Reduction Surgery (LVRS) for COPD. Tertiary care hospitals should, therefore, be encouraged to procure these instruments for the benefit of COPD patients.

PRIMARY AND SECONDARY PREVENTION OF COPD

From a pharmacotherapy point of view, many new drugs are currently in the development phase and are awaited with interest. However, the key management step is the reduction in further exposure to environmental insults. Smoking cessation for those who have developed COPD due to tobacco smoking is a crucial component of COPD management. Apart from some antidepressant drugs that have shown some promising effects on smoking cessation, the key intervention still remains proper and in-depth patient counseling. For those who have developed COPD due to exposure to indoor and outdoor air pollutants, secondary prevention is important to prevent the further progression of the disease. With the realization that exposure to biomass fuel smoke is perhaps a greater risk factor for COPD in this part of the world, primary prevention strategies in the form of patient awareness programs and governmental intervention programs through policy change may go a long way in reducing the burden of COPD.

COPD Exacerbations

COPD exacerbations, usually caused by bacterial or viral infection and exposure to air pollutants, are the single most important factor that determines the quality of life and survival of the patient. Every effort should, therefore, be made to prevent COPD exacerbations and to treat them effectively and soon enough as and when they occur. Many of these exacerbations will require the use of appropriate antibiotics, along with oral corticosteroids, bronchodilators and ventilator support, if required. Not only do these exacerbations accelerate the decline in lung function and worsen the quality of life, but they also drain off financial resources. Many need to live a life full of compromises. Patient education and pulmonary rehabilitation play a crucial role in ensuring that the patient copes up with the underlying physiological derangement and lives a better quality of life. Nonetheless, many of the COPD patients will ultimately need to be counseled about the end-of-life issues. This needs to be done very carefully with a bit of imagination, sensitivity and better communication skills.

CONCLUSION

COPD is a disease that will certainly grow in the forthcoming decades and we need to build up an action plan to halt this progress. Both primary and secondary prevention strategies need to be in place. For this, we need to educate lay people, health care providers and public health personnel. We also need to generate new knowledge to understand the risk factors better, their mechanisms and explore opportunities for new interventions that will help to reduce the suffering that is associated with this debilitating disease. We also need to improve our diagnostic abilities by increasing the use of spirometry in clinical practice. More importantly, we need to approach our COPD patients with “justified optimism” and give them the best possible care that is currently available. There is a lot we can offer to these patients than what was available before. In order to prevent COPD from becoming a major killer disease in our country, we need to develop an appropriate infrastructure and action plan that will need to be implemented carefully and meticulously. It is time to have a National COPD Control Program in place, before it gets too late.

77

Health and Economic Burden of Chronic Obstructive Pulmonary Disease

Monica Barne, Sundeep Salvi

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is one of the leading causes of morbidity and mortality in the developed as well as developing countries. It makes a person lose precious years of his life and also contributes significantly to the global economic burden. The abatement of the main risk factors for respiratory diseases, in particular tobacco smoking, environmental tobacco smoke, indoor biomass fuels, outdoor air pollution and unhealthy diet, can achieve huge heal in decreasing the disease burden.[1] Knowledge of the burden of a disease also helps in calculating the economic impact of the disease on the country so that cost-effective measures can be planned and implemented based on this understanding.

MORTALITY DUE TO COPD

Global Mortality

According to the World Health Organization (WHO), more than three million people die of COPD every year, which corresponds to almost 5% of all deaths globally. In 2002, COPD was the fifth leading cause of deaths worldwide and by the year 2030, it is predicted to become the third leading cause of deaths.[2] India alone contributes to over half a million of deaths, second only to China which is responsible for an estimated 1.3 million deaths (Fig. 77.1). The United States and Western Europe, each account for about 1,40,000 COPD deaths every year.[3] These mortality rates are projected to increase by over 30% every decade.

COPD Mortality in the United States of America

The United States has been tracking the mortality rates from various communicable and noncommunicable diseases over the last 50 years. Although coronary heart disease, cancer and stroke occupy the top three positions amongst all the causes of deaths, their mortality rates have reduced dramatically over the last three decades, unlike the mortality rates due to COPD which have, in fact, increased by over 160% (Figs 77.2 and 77.3).[4]

COPD Mortality in the Southeast Asian Region

Although tuberculosis and malaria are still major causes of death in the Southeast Asian Region, their mortality rates are anticipated to reduce from 4,00,000 and 2,00,000 per year, respectively to almost half by the year 2030[5] (Fig. 77.4). In contrast, mortality rates due to COPD, which are over two-fold greater than those due to tuberculosis currently (9,00,000), are estimated to increase by over 160% by the year 2030, which is almost similar to the increase in mortality rates of COPD in the US.

These observations clearly highlight the fact that mortality rates due to COPD are increasing both in the developed as well as developing world.[5]

COPD Mortality in India

As a result of industrialization, socioeconomic development, urbanization, changing age structure and changing lifestyles, India is facing a growing burden of noncommunicable diseases. Of all the noncommunicable diseases, chronic respiratory diseases have been shown

Fig. 77.3: Percentage change in age adjusted death rates in the United States, 1965-1998

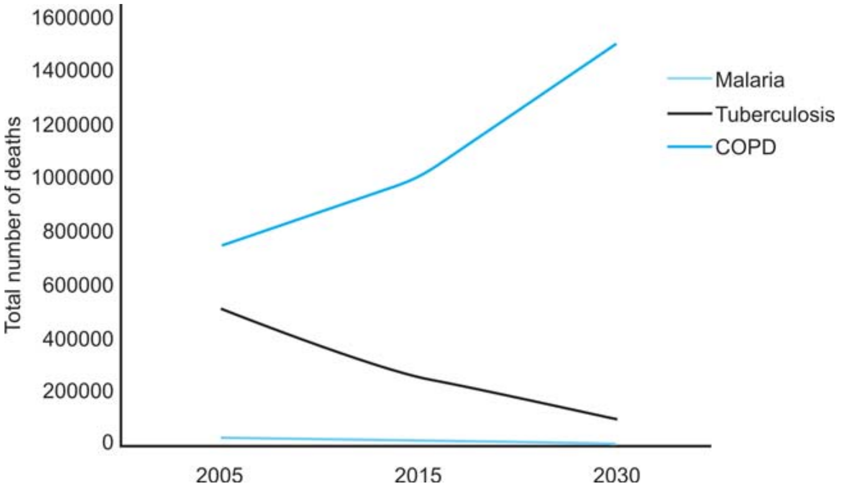

Fig. 77.4: Trends of mortality statistics in Southeast Asian Region for malaria, tuberculosis and COPD

to be the second biggest cause of mortality (5,77,837 deaths) in India, second only to injuries (Fig. 77.5).[6] The WHO estimates quote a figure of almost 5,56,000 deaths attributable to COPD in the Southeast Asian Region, which majorly comprises India.[3] Thus, almost 95% of the mortality due to chronic respiratory diseases in India can be attributed to COPD.

The above figures seem to be corroborated by another study that examined the leading causes of death in rural India.[7] The data gathered from the "Survey of Causes of Death (rural)," Annual reports of Registrar General of India (RGI), Census of India 2001, National Family Health Survey I and II and various other community-based studies clearly indicated that bronchitis and asthma were the leading cause of death in rural India (Fig. 77.6)[7] overtaking those due to coronary heart disease, cardiovascular disease and even other communicable diseases such as tuberculosis, pneumonias and gastrointestinal infections. Bronchitis and asthma together were recorded as the leading cause of death in both the sexes in all the states studied (Fig. 77.6).

Chronic obstructive pulmonary disease is primarily described by its prototype "chronic bronchitis" in most of the epidemiological studies and as per current

Fig. 77.7: Top 10 causes of death in Maharashtra, 2008

practices, COPD continues to be used interchangeably with chronic bronchitis.[8] Though COPD has now been identified as a distinct clinical entity, confusion still remains in the minds of medical practitioners, especially at primary care level. The overlap between asthma and COPD is generally difficult to resolve and several patients are diagnosed and classified as "asthma," a term which a primary care physician finds easier to understand and explain to the patient.[8]

State-wise mortality data is currently available only for Maharashtra and according to a report published by the Maharashtra State Health Systems Resource Center in 2010,[9] COPD was found to be the leading cause of deaths in Maharashtra (Fig. 77.7). Mortality due to COPD was found to be almost twice that of coronary heart disease. The report was prepared after the analysis of the statistics from the respective bureaus of the public health department; Government of Maharashtra; Health Management Information System (HMIS), which provides updated data regarding public health initiatives; the Sample Registration System (SRS); the Survey of Cause of Death (SCD); National Family Health Surveys (NFHS) and also the district level health surveys. Whilst the authenticity and reliability of the data could be questioned, it cannot be denied that COPD is indeed one of the major causes of deaths in Maharashtra and it seems likely that the situation may not be too different in the other states in India.

PREVALENCE OF COPD

Global Prevalence of COPD

Prevalence of COPD varies from country to country and within the country from region to region due to the different levels of exposure to risk factors. The most common risk factors are tobacco smoking, industrial pollution, indoor air pollution in the form of usage of biomass fuel, etc. According to the WHO, 600 million people worldwide are believed to suffer from COPD.

Several studies have estimated the prevalence of COPD in the past, but the tools for diagnosis of COPD have been largely ill defined. On one hand, prevalence based on self-reported symptoms (chronic cough, sputum, etc.) most likely overestimated the true burden of COPD.[10] In fact, it is suggested that only half of the patients with the symptoms of chronic bronchitis actually have COPD. On the other hand, physician's diagnosis in the absence of spirometry usually underestimates true COPD.[11] Salvi and Barnes have summarized all the data available on the prevalence of COPD from various countries (Table 77.1).[12]

As is evident, there is a considerable variation in the prevalence of COPD across the globe. The variations in prevalence rates may not necessarily be only due to the actual difference in prevalence in various countries but also likely depends upon the fact that the diagnostic and

research tools vary from study to study. The tools used to define COPD have included respiratory symptoms, self-reported COPD diagnosed by doctor and spirometry defined COPD (ratio between FEV$_1$ and FVC measured either before bronchodilator or after bronchodilator). Moreover, the cut-off value for the FEV$_1$/FVC ratio has also varied from study to study. Some studies have also used combinations of one or more of these tools.

There is considerable within study variation in the prevalence of COPD depending upon the criteria for defining COPD. For example, using the European Respiratory Society (ERS) definition of COPD (prebronchodilator FEV$_1$/FVC less than 0.88 for men and less than 0.89 for women) gives a prevalence of 11.0% which increases to 40%, if the American Thoracic Society (ATS) criteria is used to define COPD.[18]

Considering this wide variation in the study methodology and definitions of COPD, a worldwide study called Burden of Obstructive Lung Diseases (BOLD) has been initiated in 2002 which along with the Proyecto Latinoamericano de Investigacion en Obstrucción Pulmonar (PLATINO) study group has determined the prevalence of COPD using a standardized validated respiratory questionnaire and spirometry. A postbronchodilator FEV$_1$/FVC less than 70% on spirometry has been used to define COPD which is the Global initiative for Obstructive Lung Disease (GOLD) criteria for the diagnosis of COPD. BOLD and PLATINO together are currently developing a growing database of COPD prevalence worldwide.

The results of the BOLD study, which has been completed in 12 sites, including a population of 9,425, reported a prevalence of stage II or higher COPD of 10.1% overall (11.8% for men and 8.5% for women).[31] The prevalence increased with the age and pack years of smoking, but other less understood factors, such as

TABLE 77.2: Prevalence of COPD and its association with smoking in various population studies from India

	Population	*COPD prevalence (%)*

	Urban	4.2	1.6	2.6
Ray (1995)	South India	4.08	2.55	1.6

biomass heating and cooking exposures, occupational exposures and tuberculosis, also contributed to the location specific variations in the disease.[32]

COPD Prevalence in India

Jindal et al. performed an extensive review of all data published on COPD prevalence in India from 1964 to 1995 (Table 77.2).[33] This study provided the backbone for the estimation of morbidity and mortality of COPD in India and also helped to project the economic burden of COPD in India. As is evident, there is a wide variation in the prevalence of COPD in different parts of India, the highest being reported from North Indian rural population (9.4%). This wide variation could be explained by the wide variety in the exposure to risk factors.

The National Commission on Macroeconomics and Health in its background papers on the burden of diseases estimated that there are about 14.9 million chronic cases of COPD in India in the age group of 30 years and above and these are projected to increase by nearly 50% by the year 2016. The estimated morbidity for noncommunicable diseases in India shows that the prevalence of chronic respiratory diseases is the highest amongst other common disease states (Fig. 77.8). Out of the 65 million cases of chronic respiratory diseases, about 17 million are due to COPD. The morbidity due to COPD is expected to increase to 22.2 million by the year 2016 (Fig. 77.9).[34]

In 2006, a large multicentric field survey was conducted in both the urban as well as rural populations at Bengaluru, Chandigarh, Delhi and Kanpur with the help of a structured and validated questionnaire. Prevalence of COPD amongst the 35,295 subjects investigated (age ≥35 years) was 4.1% with a male to female ratio of 1.56:1. Prevalence of COPD in smokers was 2.65 times higher than nonsmokers, and amongst the smokers, the prevalence was higher amongst *bidi* smokers as compared to cigarette smokers (8.2% and

5.9%, respectively). Exposure to Environmental Tobacco Smoke (ETS) was associated with a 40% increased odds of COPD which increased to 57% amongst those concomitantly exposed to biomass fuel.[35]

A questionnaire-based study amongst 12,000 slum dwellers from Pune city in Maharashtra revealed an overall prevalence rate of 6.5% (8.5% in males and 4.5% in females). Amongst those diagnosed with COPD, 69% were never smokers. The overall prevalence of questionnaire-diagnosed COPD amongst the never smoker males was 6.8% and females was 4.4%. In this study, absence of a separate kitchen for cooking was an independent risk factor associated with COPD prevalence in males (OR: 1.95, $p = 0.02$) while use of kerosene fuel for cooking increased the odds of COPD in females by around 2.5 times (OR = 2.48, $p = 0.01$).[36] In a recent study from rural population in Mysore, PA Mahesh et al. reported a prevalence of 7.1% (males = 11.1%, Females = 4.5%) using a structured questionnaire.[37]

DISABILITY-ADJUSTED LIFE YEARS DUE TO COPD

Mortality estimates give us the death rates due to a disease but the morbidity that is caused by the illness with respect to the Years Lived With Disability (YLD) which would otherwise have been years of good health and productivity for that individual and the Years of Life Lost (YLL) (premature mortality) which the patient would have otherwise lived for had the disease not occurred. The World Bank had commissioned a report for the estimation of the true burden of disease for more than 100 diseases and the report was published in 1996. The true burden of disease was calculated as Disability Adjusted Life Years (DALYs), which is a sum of the YLDs and the YLL. Disability adjusted life years for a specific condition are defined as the sum of years lost because of premature mortality (YLL) and years of life lived with disability (YLD) adjusted for the severity of the disability.[3] The DALYs due to COPD by WHO region are depicted in Fig. 77.10.

A considerable degree of morbidity is attributable to COPD. Worldwide, 1.9% of the DALYs were lost due to COPD. In 1990, COPD was the 12th leading cause of DALYs lost globally and was responsible for 2.1% of the total DALYs. According to future projections, COPD will be the fifth leading cause of DALYs lost worldwide in 2020, behind ischemic heart disease, major depression, traffic accidents and cerebrovascular diseases.[38]

A total of 27,756 thousand DALYs were lost globally in 2002 (Fig. 77.10) out of which maximum morbidity was seen in the Western Pacific Region B. In the South East Asian Region D, which mainly comprises India, 6,740 thousand DALYs were lost due to COPD in the year 2002.[3] In India chronic respiratory diseases are said to account for 3% of DALYs but this is likely to be an understatement. The current information available on COPD in India is bound to increase this figure tremendously.[8]

Fig. 77.11: Economic burden of COPD in India

ECONOMIC BURDEN OF COPD

Global Economic Burden of COPD

COPD is a costly disease with very high direct costs (value of health care resources devoted to diagnosis and medical management) and indirect costs (monetary consequences of disability, missed work, premature mortality and cost of attendants or family costs resulting from the illness).[38] In the European Union, the total direct costs of respiratory diseases is estimated to be about 6% of the total health care budget and COPD alone accounts for 56% of this budget amounting to about 38.6 billion Euros.[38] In the United States, the total economic cost of COPD morbidity and mortality has been estimated at \$23.9 billion in 1993. Of this, \$14.7 billion were spent on direct treatments for COPD-related illness and the remaining \$9.2 billion were for indirect costs.[39] Similar data from another US study suggest that 10% of persons with COPD account for less than 70% of all medical care costs.[39] The National Heart, Lung and Blood Institute (NHLBI) provides an estimate of the total (direct plus indirect) annual cost of COPD in the US to \$38.8 billion. More than half of this cost (\$21.8 billion) was due to direct expenditure.[40] The perpatient direct cost (in \$US 2005) was estimated to be in the range of \$2,700–\$5,900 annually.[40]

The presence of COPD also greatly increases the total cost of care of patients, especially when inpatient costs are considered. Presence of COPD related illness costs in the United States based on the 1987 Medical Expenditure Survey were 2.7 times the expenditures for patients without COPD (\$5,409 vs \$2001). The annual per capita expenditures for people with COPD were also 2.5 times the expenditures for people without COPD.[38]

The GOLD also states that in developing countries, direct medical costs may be less important than the impact of COPD on the workplace and home productivity. As the health care sector may not provide long-term supportive care services for severely disabled individuals, COPD may force two individuals to leave the work place—the affected individual and a family member who must now stay home to care for the disabled relative. Since human capital is often the most important national asset for developing countries, the indirect costs of COPD may represent a serious threat to their economies.

Economic Burden of COPD in India

According to National Commission on Macroeconomics and Health published data, the per capita expenditure on COPD was ` 42,664 in 2006 and is expected to increase to ` 62,630 in 2016. Figure 77.11 depicts the huge economic burden of COPD on India. India spent an estimated ` 25,209 crores for COPD (direct and indirect costs) in the year 2006 and this cost is expected to increase to ` 35,337.7 crores in the year 2011. A large part of this expenditure is because of delayed diagnosis and improper management.[34]

CONCLUSION

The incidence and prevalence of COPD is fast increasing, not only in the industrialized countries but also in developing countries due to the ever increasing smoking epidemic compounded by poor socioeconomic status in countries like India and China. It has been estimated that almost 50% of smokers may develop COPD.[41] In addition, nonsmoking COPD caused mainly due to exposure to smoke from biomass fuel, occupational exposure to dust and gases, poor socioeconomic status, etc. is fast emerging as an entity that is causing considerable morbidity and mortality amongst nonsmokers too.[13] The fact that the mortality rates due to COPD in India is the second highest in the world and the huge economic burden of the disease on the country indicates that India needs to take aggressive measures to prevent the development of COPD and calls for major policy changes to equip the health care system with facilities for early diagnosis and appropriate management of COPD.

Risk Factors for Chronic Obstructive Pulmonary Disease

Sneha Limaye, Sundeep Salvi

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is a chronic lung disease that is largely driven by environmental factors, although genetic susceptibility is also important. Risk for COPD is related to an interaction between genetic factors and many different environmental exposures, which could also be affected by comorbid diseases. Tobacco smoking is an age old established, major risk factor for COPD, but emerging evidence suggests that risk factors other than smoking are strongly associated with COPD.[1,2] These factors include exposure to indoor and outdoor air pollutants, workplace exposure to dust and fumes, history of repeated lower respiratory-tract infections during childhood, history of pulmonary tuberculosis, chronic asthma, intrauterine growth retardation, poor nourishment and poor socioeconomic status. The identification of risk factors is an important step toward developing strategies for prevention and treatment of any disease.

TOBACCO SMOKING

Tobacco smoking was first shown to be associated with the risk of developing COPD during 1950's.[3,4] When Fletcher and Peto reported that lung function decreased markedly in those smokers who had symptoms of chronic cough and/or breathlessness.[5] A subsequent larger and longer Framingham cohort offspring study confirmed these results.[6] All subsequent research then focused on smoking as the most important risk factor for COPD and several prevalence studies, in fact, have been done only amongst smokers. Currently, clinical trials in COPD recruit only smokers with at least 20 pack years of cigarette smoking exposure.

Tobacco smoking is highly prevalent in the developed countries, although the number of smokers is now declining slowly. On the other hand, the number of smokers in the developing countries is increasing rapidly. It is estimated that by 2030, tobacco consumption in any form will account for 10 million deaths per year, half of them aged 35–69 years. Almost 82% of world's smokers reside in the developing countries and nearly 17% of world's smoking population resides in India.[7] In India, an estimation of 65% of all men and 33% of all women use some or other form of tobacco. According to 55th round (1999–2000) of NSS in India, 54% of tobacco consumers consume *bidi*, 15% consume cigarette and 30% consume different tobacco chewing products. The prevalence of smoking in the Indian population is 28.5% in men and 2.1% in women.[8] There was, however, a wide range of the prevalence rate of smoking from the lowest of 13.9% in Punjab to the highest of 49.4% in Mizoram. *Bidi* was the most common form of smoking, more so in the rural areas. The different forms of tobacco smoking prevalent in India are cigarette, *bidi*, *hookah* and *chillum* smoking.[8]

In India and other Southeast Asian countries, *bidi* smoking is more common than cigarette smoking. *Bidis* are made up of tobacco wrapped in tendu leaf (Fig. 78.1). Although the amount of nicotine in a *bidi* is one-fourth that of a cigarette, the amount of tar is roughly five times greater. From COPD point of view, one *bidi* is as harmful as one cigarette. Due to the low combustibility of the tendu leaf wrapper, *bidi* smokers inhale more often and more deeply, thereby breathing greater amounts of tar.[9]

Fig. 78.1: *Bidis* are more popular form of smoking than cigarette

Cigarette smoke is a complex mixture of over 4,700 chemical compounds, generates high concentration of free radicals and oxidants like Reactive Oxygen Species (ROS), epoxides, peroxides and Nitric Oxides (NO).[10] Cigarette smoke contains two very different populations of free radicals, one in the tar and one in the gas phase. The tar phase contains several relatively stable free radicals, the principal radical being quinone/hydroquinone (Q/QH_2). The gas phase of cigarette smoke contains small oxygen and carbon-centered radicals that are more reactive than are the tar-phase radicals. One of the important mechanism through which tobacco smoke exerts its harmful effects on the lungs is the oxidative stress caused by reactive oxygen species.

Cigarette smoke contains 10^{17} oxidants per puff, of which 10^{14} are oxygen free radicals, which have the potential to produce an enormous oxidant burden on the lungs.[11] All tissues are vulnerable to oxidant damage, but by virtue of its location, the airspace epithelium is particularly vulnerable. Tobacco smoking increases the risk of COPD by 2–3 folds, although not all smokers develop COPD. Some of the earlier reports estimated that only 15% of smokers develop COPD. However, new evidence suggests that up to 50% of smokers develop COPD.[12] The risk of COPD also occurs amongst people who are exposed to second-hand smoke.[13,14]

INDOOR AIR POLLUTION AS A RISK FACTOR FOR COPD

It is estimated that about half of the global population (3 billion people) live in homes that use biomass fuel for cooking and heating purposes. Burning of biomass solid fuel (includes wood, twigs, crop residues and animal dung) emits very high levels of indoor air pollutants, both particulate matter as well as the gaseous pollutants (Figs 78.2A to C). Many of these homes are poorly ventilated, exposing these individuals to very high levels of indoor air pollutants.

Women, young girls and small children are exposed for the longest duration because they spend more time in close vicinity to the biomass smoke. During their lifetime, women are exposed for around 30–40 years, which is equivalent to 60,000 hours of exposure to biomass smoke or inhaling a total volume of 25 million liters of highly polluted indoor air.[15] The levels of indoor air pollutants, encountered in homes that use biomass fuel, are several orders higher than the levels in the most polluted urban cities in the world. These pollutants have the potential to produce intense oxidative stress in the lungs and the elastolytic effects of these pollutants have been found to be worse than those caused due to tobacco smoke. The exposure to biomass smoke induces the same amount of risk of developing COPD as tobacco smoke.

Figs 78.2A to C: Sources of different biomass fuels. (A) Dung cake. (B) Crop residues. (C) Firewood

As 3 billion people are exposed to biomass smoke worldwide as compared to 1.1 billion smokers, biomass smoke is likely to be the biggest risk factor of COPD.[15]

OUTDOOR AIR POLLUTION AND COPD

Ambient air pollution is a growing problem in most urban cities of the world. Over the last few decades, air pollution in most cities in the developed countries has decreased appreciably due to the advent of strict legislation and improvements in engine technology, but it continues to increase markedly in most of the cities of the developing countries. Both the gaseous and particulate matter components of urban ambient air pollutants have been shown to be associated with increasing respiratory morbidity and cardiovascular mortality.

One of the earliest studies that investigated an association between ambient air pollution and COPD was by Fairbairn[16] in 1958, who reported that postmen from England and Wales who worked in areas with higher outdoor air pollution levels, had a greater prevalence of COPD than those who worked in areas with lower ambient air pollution levels. A subsequent study from the United Kingdom showed that postmen who worked in more polluted cities had lower lung function values than those who worked in less polluted areas.[17] Similar observations were later reported in the general population.[18] More recently, living in areas closer to roads with heavy motor vehicular traffic have been shown to be associated with significant decrements in lung function,[19] and increased prevalence of COPD in women.[20]

Although there is a good evidence to suggest that the high levels of outdoor air pollutants increase COPD exacerbations and worsen preexisting COPD,[21] we do not have conclusive evidence to support the argument that outdoor air pollutants are responsible for causing new cases of COPD. Clearly, large, multinational, prospective epidemiological studies are needed to investigate this important question.

COPD ASSOCIATED WITH OCCUPATIONAL EXPOSURES

The association between occupational exposures and COPD has been observed for at least four decades. Earlier studies revealed that exposure to toxic gases at workplace,[22] grain dust in farms,[23] and to dust and fumes in factories,[24] were strongly associated with the risk of development of COPD. In 2003, the American Thoracic Society conducted a systematic epidemiological review of occupational factors associated with the development of COPD and reported that approximately 15% of COPD may be attributable to workplace exposure.[25] A more recent follow-up of the review has provided similar estimates.[26]

Farming as an occupation has been shown to be strongly associated with COPD. In their study of 1,258 adults of above the age of 40 years, Lamprecht et al.[27] investigated the association between farming and COPD prevalence [defined by a postbronchodilator Forced Expiratory Volume in One Second/ Forced Vital Capacity (FEV_1/FVC) ratio less than 0.70 on spirometry] and reported that the risk of COPD, attributable to farming, was 7.7% and that around 30% of the farmers had at least mild COPD. More recently, a study from Norway,[28] demonstrated that livestock farmers, compared to crop farmers, had a 40% greater risk of having COPD (95% CI: 10% to 70%) and that this correlated strongly with the levels of ammonia, hydrogen sulfide, inorganic dust and organic dusts measured by personal monitors at workplace.

Longitudinal studies have documented the association between COPD and occupational exposures in coal miners, hard rock miners, tunnel workers and concrete manufacturing workers. In heavily exposed workers, the effect of dust exposure may be even greater than that of cigarette smoking alone.[29] Construction workers exposed to fumes and mineral dust have been shown to have a significantly higher risk of death due to COPD.[30] Prolonged exposure to silica in occupations, such as the construction industry, brick manufacturing, gold mining and in iron and steel foundries (where average respirable dust levels reach up to 10000 $\mu g/m^3$), is also strongly associated with the development of COPD.[31] The burden of occupational COPD is likely to be high in countries of low and middle income, where occupational exposures to dust and fumes could be greater than in high-income nations, because of less stringent laws and lack of adequate facilities for reducing the exposures.

COPD ASSOCIATED WITH PULMONARY TUBERCULOSIS

Pulmonary tuberculosis (Fig. 78.3) has been shown to be associated with chronic airflow obstruction, particularly of the COPD phenotype, at the time of diagnosis,[32,33] during treatment,[34] and several years after the completion of treatment.[35] The amount of airflow obstruction is related to the extent of the disease determined

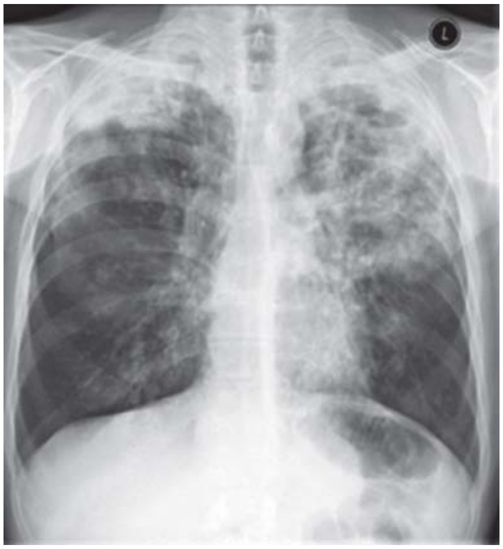

Fig. 78.3: Pulmonary tuberculosis as a risk factor for COPD

radiologically, the amount of sputum produced and the length of time after the diagnosis or completion of treatment.[36] Apart from the airway fibrosis that may follow tubercular infections, the immune response to mycobacteria may enhance the airway inflammation that is typical of COPD.

The prevalence of airflow obstruction in subjects with pulmonary tuberculosis has been shown to vary from 28 to 68% according to the study design, timing of assessment and medical or surgical treatment. In a nationwide household survey of 13,826 adults in South Africa, the strongest predictor of COPD, defined by self-reported symptoms of a chronic productive cough, was history of pulmonary tuberculosis. The odds ratios were 4.9 (95% CI 2.6–9.2) for men and 6.6 (95% CI 3.7–11.9) for women.[37] More interestingly, this risk was stronger than the odds ratios associated with tobacco smoking or exposure to biomass fuel smoke.

More recently, a study from five cities in Colombia (PREPOCOL Study)[38] that investigated the association between history of pulmonary tuberculosis and COPD (defined by postbronchodilator FEV_1/FVC ratio <0.70), reported a strong association with an odd ratio of 2.9 (95% CI 1.6–5.5). Further, this association was even stronger than that noted with tobacco smoking [OR: 2.6, (95% CI 1.9–3.5)].

The above studies from South Africa, Colombia, India and Latin America indicate that a history of pulmonary tuberculosis is a strong risk factor for COPD. More than 2 billion people, equal to one-third of the world's population, are infected with tubercle bacilli and an estimated 9.2 million new cases of tuberculosis are detected every year; 80% of them are present in 22 countries of the world.[39] Countries from Asia, Africa and Latin America have a particularly high burden of pulmonary tuberculosis. The cumulative burden of COPD associated with pulmonary tuberculosis is, therefore, likely to be much greater than previously believed, especially in the developing countries.[40]

CHRONIC ASTHMA AS A RISK FACTOR FOR COPD

Poorly treated chronic persistent asthma or poorly treated severe asthma can lead to changes in the lungs that are comparable to those caused by smoking.[41] In patients with severe asthma, the inflammation in the airways becomes more similar to the pattern seen in COPD, with an increase in the number of neutrophils and Interleukin-8, increased proteases, increased oxidative stress and a reduced responsiveness to corticosteroids.[42] This might reflect common mechanisms between COPD and asthma that are related to the intrinsic determinants of disease severity.

In a 5-year longitudinal study of 10,952 subjects, it was found that those with a new asthma diagnosis had lower initial values of lung function and an increased rate of decline in FEV_1 compared to nonasthmatic subjects.[43] Subsequent analyses from the same study after 15-years of follow-up showed that subjects with self-reported asthma still had a greater decline in FEV_1 over time than those who did not.[44] In a cohort of 3,099 adult subjects from Tucson, USA, that were followed-up for 20 years, it was seen that after adjusting for age, sex, smoking, Immunoglobulin E (IgE) and skin test reactivity, physician-confirmed active asthma was significantly associated with the subsequent risk of development of COPD.[45] Active asthmatics were 10 times more likely to acquire symptoms characteristic of chronic bronchitis and 17 times more likely to receive a diagnosis of emphysema by a physician. In this cohort, asthma was found to be the strongest risk factor for subsequent COPD [hazard ratio (HR) = 12.5; attributable risk (AR) = 18.5%], more than even tobacco smoking [hazard ratio (HR) = 2.9; attributable risk (AR) = 6.7%]. Primary care clinicians who practice long enough often report patients with acute bronchitis that morphs into chronic asthma that then develops into severe COPD.[46]

Poorly treated chronic persistent severe asthma may present with the features of COPD in the subsequent years. In many regions of the developing world as well as some parts of the developed world, asthma still remains poorly treated; it is likely that this may contribute significantly to the global burden of COPD.

TABLE 78.1: Genes implicated in COPD

Genes for which association studies have shown a significant relationship between polymorphisms and COPD	*Candidate genes for which there are no significant associations at present*
Alpha1-antitrypsin	Extracellular superoxide dismutase
Alpha1-antichymotrypsin	Secretory leucocyte leukocyte proteinase inhibitor
Cystic fibrosis transmembrane regulator	Cathepsin G
Vitamin D-binding protein	
Alpha 2-macroglobulin	
Cytochrome P450A1	
ABH secretor, Lewis and ABO blood groups	
HLA	
Immunoglobulin deficiency	
Haptoglobin	

COPD: Chronic obstructive pulmonary disease; HLA: Human leukocyte antigen.

GENETIC FACTORS

Although COPD is predominantly an environmental lung disease, it is clear that genetic susceptibility is also important. Recent studies have indicated that COPD can run in families, and for this several potential genes have been identified[47] (Table 78.1).

Though several genes have been implicated in COPD, work done to examine specific polymorphisms for the development of disease has been, at best, inconsistent, functional genetic variants influencing the development of COPD have not been yet definitively identified.

The best known genetic factor linked to COPD is deficiency of alpha 1-antitrypsin, a major circulating inhibitor of serine proteases, which arises in 1 to 3% of patients with COPD. Having low concentrations of this enzyme, particularly in combination with smoking or other pollutant exposures, increases the risk of developing panlobular emphysema. This rare recessive trait is most commonly seen in individuals of Northern European origin.

More recently, work is underway to study the role of antioxidant genes as potential candidates for increasing genetic susceptibility. There are several antioxidant genes, which play a major role in protecting the airways and lung parenchyma from environmental oxidative stress and a genetic defect in the production of these protective molecules may increase susceptibility to develop COPD.

SOCIOECONOMIC STATUS

Poor socioeconomic status is a risk factor independently associated with COPD and is likely to be indicative of other factors such as intrauterine growth retardation, poor nutrition (low intake of antioxidants), housing conditions, childhood respiratory tract infections, exposure to tobacco smoke, occupational risks, and biomass smoke and other indoor air pollutants. These factors might collectively contribute to the risk of COPD.[18] Socioeconomic status should therefore be treated as an independent risk factor for COPD.

Pathophysiology of Chronic Obstructive Pulmonary Disease

Bill Brashier, Sundeep Salvi

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is a disease syndrome characterized and defined by a single physiological parameter, limitation of expiratory airflow, which is accompanied by loss of lung elastic recoil, fibrosis, edema of the airways, intraluminal accumulation of secretions and bronchial smooth muscle contraction. Most often, these changes are slowly progressive over years. According to the current Global Initiative of Obstructive Lung Disease (GOLD) COPD is defined as a "disease characterized by chronic airflow limitation and a range of pathological changes in the lungs, some significant extrapulmonary effects and important comorbidities, which may contribute to the severity of disease in individual patient,"[1] and most interestingly with our improved understanding of pathogenic mechanisms, COPD now considered to be largely preventable and to a certain extent treatable.

Pathogenesis–Evolution of Concepts

All these changes in COPD are caused by a cascade of multiple complex inflammatory mechanisms occurring in the lung in response to chronic exposure to air pollutants, infections and various other risk factors. The first evidence of COPD dates back to 1679 where COPD (defined as emphysema at that time) was first described as voluminous lung or turgid lung occurring as result of trumpet blowing.[2] In 1814, Badham described this disease as associated with chronic cough and mucus hypersecretion and called this disease "Chronic bronchitis."[3] With the discovery of the stethoscope, Laennec gave a more vivid description of this disease as air entrapment in the lungs, which was caused not only by smoking, but also occurred in nonsmokers, especially those with familial predisposition, and suggested that the disease was very commonly prevalent in the general population.[2] Most of the earlier understanding of COPD was based on physiological and postmortem gross pathological observations. However, very little was known about the cellular and molecular changes of the disease, hence there was no optimal treatment available.

The first stride in our understanding of pathogenesis came in 1964 when Gross et al. first demonstrated the protease-antiprotease animal model for emphysema. He suggested that emphysema was a disease caused by over production of proteases enzyme in the lung parenchyma accompanied by reduced antiprotease activity that caused the alveolar wall destruction and development of emphysema.[4] Thereafter, over the next 50 years, understanding of the pathogenesis of COPD has advanced significantly, and new concepts still continue to emerge. Today it is clear that neutrophils, macrophages and T lymphocytes along with various inflammatory mediators and proteases are the primary culprits in the pathogenesis of COPD. New concepts of protease/antiprotease imbalance, steroid tolerance, amplified oxidative stress, autoimmune character of COPD, disease of accelerated aging of the lung and more recently systemic inflammation have emerged, which are instrumental in altering the management in COPD patients and have given novel insights for new drug discoveries for this chronic disease.

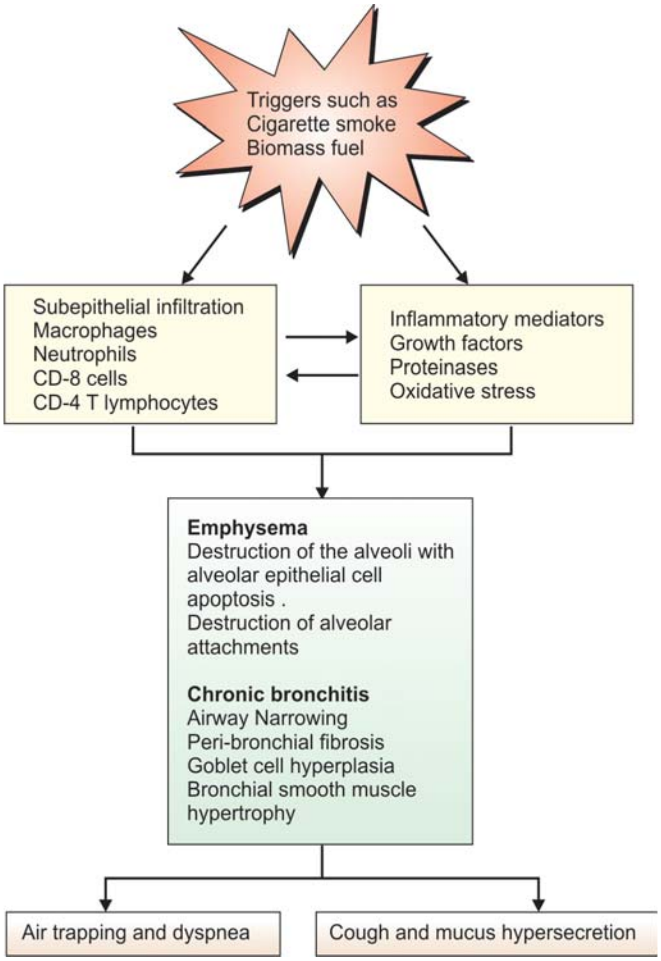
Pathophysiological Changes

The pathology of COPD is characterized by certain morphological and cellular changes occurring in the airways and lung parenchyma due to ongoing chronic inflammatory processes. Pathological changes, such as subepithelial infiltration of mononuclear cells (macrophages, CD8+ T lymphocytes), mucous gland hypertrophy and inflammation, subepithelial infiltration of eosinophils (during exacerbations of COPD), subepithelial infiltration of neutrophils, goblet cell hyperplasia, smooth muscle hypertrophy, wall fibrosis and destruction of the alveolar attachments, tend to occur in both proximal and peripheral airways of the lungs. Further, the inflammation of COPD also causes lung parenchymal changes, such as, destruction and enlargement restricted to the respiratory bronchioli and the central portion of the acinus (centriacinar emphysema), destruction and enlargement uniformly involving the whole acinus (panacinar emphysema) and infiltration of CD8$^+$ T lymphocytes (Fig. 79.1).

The basic pathophysiologic consequences of COPD inflammation consists of increased resistance to airflow, loss of elastic recoil and decreased expiratory flow rate. The alveolar walls frequently break because of the increased resistance of air flows and increased apoptosis of the alveolar epithelial cells. Consequently, more effort is required for the air to be exhaled, which happens mostly due to narrowed airway and pressure changes in the thorax. These physiological changes cause earlier closure of small airways resulting in more air trapping in the lungs. Further, hyperinflated lungs flatten the curvature of the diaphragm and enlarge the rib cage. The altered configuration of the chest cavity places the respiratory muscles, including the diaphragm, at a mechanical disadvantage and impairs their force-generating capacity. This results in increase in the metabolic work of breathing, and the sensation of dyspnea heightens (Fig. 79.1). All these changes occur due to inflammatory cells and mediators, which are increased in COPD.

Role of Neutrophils in COPD

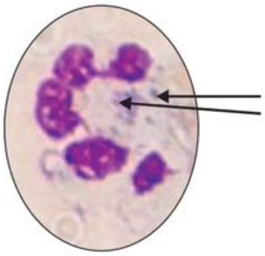
The neutrophil has been highly acclaimed as a key effector cell in the recalcitrant pathogenesis of COPD. Its role was first identified in 1963, when it was recognized that the deficiency of an endogenous inhibitor of serine proteases, alpha-1-antitrypsin was an important cause of early onset severe asthma.[5] This coincidental observation led to the proteinase/antiproteinase theory of the pathogenesis of emphysema that is now accepted widely as a key mechanism of the disease development.[6-10] The presence of neutrophils has been inversely correlated with prebronchodilator and postbronchodilator FEV$_1$, with the strongest correlation in patients without bronchodilator reversibility.[11,12] Moreover, neutrophilic inflammation has been primarily implicated in steroid nonresponsiveness in COPD.[13,14]



Triggers such as
Cigarette smoke
Biomass fuel
Subepithelial infiltration
Macrophages
Neutrophils
CD-8 cells
CD-4 T lymphocytes
Inflammatory mediators
Growth factors
Proteinases
Oxidative stress
Emphysema
Destruction of the alveoli with alveolar epithelial cell apoptosis .
Destruction of alveolar attachments
Chronic bronchitis
Airway Narrowing
Peri-bronchial fibrosis
Goblet cell hyperplasia
Bronchial smooth muscle hypertrophy
Air trapping and dyspnea
Cough and mucus hypersecretion

Fig. 79.1: Pathological changes occurring in COPD

This polymorphonuclear leukocyte originates from the bone marrow and passes through a series of developmental stages, including promyeloblasts and myeloblasts before attaining its fully differentiated form. It is at these stages when all the destructive proteinases secreted by the neutrophils develop and stay in a dormant state as azurophilic granules till the cells are further activated (Fig. 79.2).[15] The mature neutrophils survive in the systemic circulation for approximately 12 hours before undergoing apoptosis.[15] The neutrophils easily flow through the systemic vasculature except the



Azurophilic Granules containing:

- Myeloperoxidase,
- Bactericidal/permeability increasing protein (BPI)
- Defensins
- Serine proteases, e.g. proteinases 3
- Neutrophil elastase
- Cathepsin G, cathepsin B
- MMPs, e.g. MMP 9, MMP1, MMP3, MMP 12

Fig. 79.2: Neutrophil

pulmonary capillary bed, where it has to negotiate its shape and size to traverse through the much narrower pulmonary capillaries. Radiolabeled studies indicate that the journey of neutrophil across the pulmonary capillary bed is sluggish when compared to Red Blood Cells (RBCs), and the neutrophils need to deform themselves to traverse the full pulmonary capillary until the postcapillary venule.[16,17] This causes a large amount of neutrophils to remain naturally sequestrated in the lungs, where they are believed to provide active defense mechanisms against the environmental pollutants and pathogens.[17] This sequestration in the pulmonary capillaries allows time for the neutrophils to interact with capillary endothelium resulting in their transmigration across the pulmonary capillary membrane to the interstitium and airspaces of the lungs when triggered by inflammatory mediators and infections such as those seen in COPD (Figs 79.3 and 79.4).[17]

In order to enter the lungs, the neutrophils first adhere to the endothelial surface of the pulmonary capillaries through adhesion molecules and then migrate into the lungs where they survive for one to two days. The Cell Adhesion Molecules (CAMs) serve as ligands for leucocyte cell receptors, mediating the adhesion of neutrophils to the endothelium prior to their subsequent extravasation into inflamed tissue of lung.[18,19] In COPD, there is an increased migration of neutrophils into the lungs. This may occur due to enhanced neutrophil recruitment and/or delayed tissue clearance. Neutrophil accumulation in tissues is a dynamic process that is governed by both rate of neutrophil recruitment from the bloodstream and their rate of clearance from the lung tissue by lymphatics (Fig. 79.3).

Studies have described abnormalities in the circulating neutrophils of patients with COPD that can facilitate their recruitment to the lungs. The cigarette smoke, which is the major risk factor of COPD attenuates the property of deformity of neutrophils, which is required by them to negotiate their streamline pathway into the pulmonary vasculature.[19-21] The exact mechanism for such physiological consequences is not yet known; however, in vitro studies have shown that chronic tobacco smoke exposure can alter the kinetics of proteins such as filamentous actin (F-actin), which constitutes the major cytoskeleton and contractile apparatus of neutrophils.[21] This neutrophil stiffness impedes their already compromised flow in the lung capillaries. As a result their contact with the capillary endothelium is prolonged, which enhances their transmigration into the lungs even without adhesion molecules. Furthermore, in COPD there is also increased expression of adhesion molecules in both the endothelium as well as neutrophils cell surface, which enhances their migration into the lungs. It has been suggested that the initial phase of inflammation in COPD appears to be triggered by the expression of leukocyte-endothelial adhesion molecules in the lungs. Increased levels have been shown of various cellular adhesion molecules such as Intercellular Cellular Adhesion Molecule-1 (ICAM-1), endothelial adhesion molecules (E Selectin) which are all increased in the Bronchoalveolar Lavage (BAL) and systemic circulation of COPD subjects (Fig. 79.3).[22-30]

The inflammatory cells including neutrophils, release various cytokines and chemoattractants such as Interlukin-8 (IL-8),[31] LTB_4,[32] Matrix Metallopeptidase-9 (MMP-9)[33] and neutrophil elastase,[8,9,10] which provide a suitable milieu for the relentless migration of neutrophils and other inflammatory cells into the lungs and keep the intractable inflammation of COPD ongoing even after the risk factors or triggers are removed.

Once the activated neutrophils enter the lung parenchyma, they start releasing a battery of serine proteinase from the dormant azurophilic granules, which contributes to the destruction of the lung elastic tissue, ultimately leading to pathological changes such as chronic bronchitis and emphysema. There is also evidence to suggest that the neutrophils from the COPD subjects have greater chemotactic responses and greater ability to digest the surrounding tissue than the neutrophils of normal subjects indicating fundamental differences in the neutrophils of COPD.[34]

The four major neutrophilic proteases, which damage lung elastic tissues are neutrophil elastase, proteinase-3, cathepsin G and cathepsin B.[8,9,10,35] These enzymes have been shown to produce emphysematous and chronic bronchitis changes in various experimental models of COPD. The primary role of these proteolytic enzymes is to generate a pathway for the movement of leukocytes into the tissue and in this process they unsparingly degenerate the elastic connective tissue of the lung

parenchyma leading to emphysema. This happens despite the activation of natural repair process of reaccumulation of elastin.[22-30] As neutrophils move in close proximity to connective tissue, they degrade these structures, which can be reduced, but not prevented by another protein called alpha-1-antitrypsin (α-1-AT). Alpha-1-antitrypsin is an endogenous inhibitor of neutrophil elastase, and its deficiency is accompanied by severe emphysema seen in COPD, which develops in younger age. Approximately 1% of all COPD are due to alpha-1-antitrypsin deficiency. The normal levels of alpha-1-antitrypsin in the plasma are 1.5–3.5 g/l and

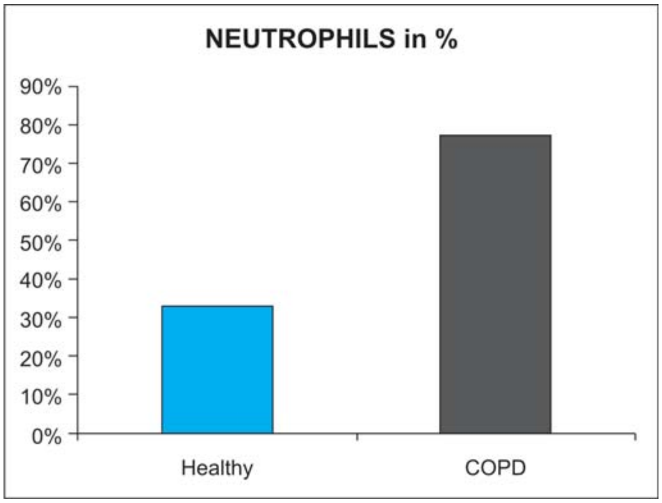

Fig. 79.4: Percentage of neutrophils in bronchoalveolar lavage of COPD versus healthy subjects (Adapted from Rato Djukanovic et al; Atlas of induced sputum. An Aid for research and Diagnosis: Parthenon Publishing; 2004; Chapter 5, pp. 71)

levels below 40 to 60% of this range are strongly associated with the development of emphysema. There is also evidence to suggest that neutrophil elastase activates matrix metalloproteinases (MMPs), which digest collagen and elastin.[36]

Neutrophil proteases also cause changes in the bronchi to produce the features of chronic bronchitis; it damages the airway epithelium,[37] causes mucus gland hyperplasia,[38] reduce the ciliary beating,[35] increases mucus secretion[39] and compromises the immunity of the airways by cleaving the C3bi opsonophagocytic receptors[39] and causes Immunoglobulin degradation, giving rise to chronic bacterial colonization of the airways.

In the healthy lung tissue there are inhibitors, which counteract the proteases activities for the enzymes released from inflammatory cells, and these include Secretory Leukoprotease Inhibitor (SLPI),[40,41] and in normal circumstances a balance is maintained between proteases and antiproteases levels in the lung. It has been proposed that in COPD the concentration of elastase released from the azurophil granule is so elevated that it cannot be totally inhibited by the normal surrounding concentrations of inhibitors. There has been growing interest in aiming to restoring this balance in the lungs of COPD with the help of several different intervention strategies that seem to have promising prospects for future therapy in COPD management.[41]

Role of Macrophages in COPD

Macrophages are cells, which are ubiquitously present in the lungs and serve as an important defense mechanism against particulate matter and pathogens that invade the lower respiratory tract. These cells are derived from peripheral blood monocytes, which migrate into the lungs where they mature into macrophages. The environmental toxins and noxious particles, which are inhaled into the lungs are usually cleared by these cells, thus preventing the lungs from being exposed to the harmful affects of these substances. Macrophages also engulf the antigens and present them to various other immune cells via different immunological mechanisms.[36] Sputum and BAL studies have shown that during chronic inflammatory conditions, such as COPD and exposure to cigarette smoke there is a 5 to 10 fold increase in the numbers of macrophages in the lungs, which are more concentrated in the centriacinar zones where emphysema is most marked, where they are likely to play a role in initiation, modulation and eventually termination of inflammatory response that characterize COPD.[42-45] Macrophage may tend to survive much longer as long as 2 years in some smokers. Macrophages are also important source of many inflammatory mediators and growth factors, which play an important role in the pathology of COPD and repair of damaged tissue.[36]

There is a positive association between macrophage numbers in the alveolar walls and the presence of mild-to-moderate emphysema as well as the degree of small airways obstruction seen in patients with COPD.[45] The slow progression and chronicity of COPD parallels the chronic increase in the numbers macrophages that is seen at sites of tissue damage/injury and supports the concept that macrophages are, at least in part, responsible for the pathologic consequences.[36] Some animal studies have also shown that chronic exposure to cigarette smoke can induce increased expression of collagen digesting enzymes in the macrophages.[46,47] Notably, the stubborn character of COPD inflammation and its poor response to steroids is majorly attributed to the evidence that the alveolar macrophages in COPD appear to be resistant to the anti-inflammatory effects of corticosteriods and this is linked to reduced activity and expression of histone deacetylase-2, a nuclear enzyme that switches off inflammatory genes activated through the transcription factor Nuclear Factor-kappa B (NF-κB).[48,49]

It is unclear whether increased numbers of macrophages in COPD are because of sequestration to facilitate lung repair or whether the normal transmigration process has failed. In usual circumstances the major role of a macrophage is to migrate to the site of the pathogen and phagocytosize it. These are then further removed from the lungs by mucociliary system and pulmonary lymphatics. But, in COPD these mechanisms seem to be impaired and hence macrophage clearance does not match pulmonary macrophage accumulation, reflecting continuous elevated sequestration triggered by the affects of cigarette smoke. The presence of macrophages in the lungs could also be attributed to the constant repair, which is needed to counteract the ongoing destruction of the lung tissue by various inflammatory mediators and protienases in COPD.

The macrophages in COPD have dysfunctional phagocytosis and lytic mechanisms, they macrophages ineffectively remove noxious substances from the lungs, which further triggers the migration of more macrophages from the peripheral blood into the organ. Further this means there may be the inadequate clearance of neutrophils by macrophage apoptosis and the release of neutrophil proteinases during necrotic neutrophil cell death. This can have devastating consequences. Moreover, dysfunction in macrophages makes a COPD subject more susceptible to invading triggers and microorganisms with subsequent increase in the frequency of exacerbations, which aggravates the pathophysiology of the disease.[50,51] The bacterial colonization of the respiratory tract and frequent exacerbations of COPD have been primarily attributed to the defective phagocytosis of the macrophages seen in COPD. The evidence indicates that alveolar macrophages from COPD patients phagocytose fewer apoptotic epithelial cells and pathogenetic bacteria, such as *Escherichia coli, Streptococcus pneumoniae and Haemophilus influenzae* compared to both nonsmokers and smokers without COPD.[52-58]

Alveolar macrophages from COPD patients have an increased baseline and stimulated secretion of inflammatory proteins, including certain cytokines and chemokines such as IL-8, IL-6, IL-10 TNF-α, LTB_4, etc. and reactive oxygen species, which account for all of the pathophysiological features of COPD. These mediators in turn, stimulate the recruitment of other inflammatory cells such as neutrophils and CD8 Lymphocytes into the lungs.[59,60] The macrophage also has enormous proteolytic potential, involving many classes of enzymes with broad ranges of substrate specificity. The secretion of proteinases by other inflammatory cells, as well as resident structural cells into the same extracellular environment may provide a potent proteinase cocktail that overwhelms the native inhibitors. If such proteinase activity remains unopposed, it is likely that the connective tissue matrix is continually abraded in the vicinity of these inflammatory cells. Macrophages also engulf the neutrophil elastase released from the neutrophils and stores them for further degradation of the matrix.[61,62]

The major interest in the macrophages in the pathogenesis of COPD is essentially due to their ability to release series of proteinases, particularly MMPs (Fig. 79.5) and series of elastinolytic cysteine proteinases, such as cathepsin K, L and S, which have potential elastolytic properties.[33,36,63] Matrix metalloproteinases are zinc- and calcium-dependent proteinases, which are known to degrade the matrix particularly the broad range of connective tissue that has an important role in tissue development and remodeling of the damaged tissue. Although released from macrophages, they are activated by serine proteinases released from neutrophils. These proteinases also inactivate Tissue Inhibitors of MMPs (TIMPs), leading to elevated MMP activity. This in turn enables the autoactivation of other latent MMPs progressing to the cascade of ongoing proteases destruction.[43,64]

Fig. 79.5: Role of macrophages in tissue destruction seen in apoptosis through MMPs

Alveolar macrophages have also been shown to release Neutrophil Elastase (NE) over a period of time *in vitro*. Although, NE is not synthesized in macrophage, it is internalized into the cell by receptor-mediated processes. Macrophages, therefore, may epitomize a store for neutrophil elastase. Although, this property is very similar to ravaging NE, but unlike NE, which is rapidly released from azurophilic granules of neutrophils, the MMPs are more strictly regulated to cellular environment and their expressions are modified by cytokines and various growth factors.[36] Some of the major MMPs found in the inflamed lung environment of COPD patients are MMP-2, MMP-9, MMP-12 and MMP-14. The MMP-2 and MMP-9 have very strong gelatin digesting and elastolytic properties respectively, while MMP12 is implicated in the earlier stages of COPD (Fig. 79.5). [33,45,65-69]

Role of T Lymphocytes in COPD

The first evidence of the role of T lymphocytes in the pathogenesis COPD was demonstrated in 1995, wherein the correlation between the number of T lymphocytes in the lung and extent of emphysema was first revealed.[69,70] It was also realized that the inflammation of COPD was not only limited to the innate immune mechanisms, but also involved adaptive immunity with the infiltration of $CD8^+$ and $CD4^+$ cells not only in the alveolar wall and small airways, but also in the adventia of pulmonary vasculature, indicating the importance of these cells in the development of pulmonary hypertension related to COPD. Subsequent studies have further shown that although both the $CD4^+$ and $CD8^+$ cells are increased in the airways and the lung parenchyma of the patients with COPD, it is the $CD8^+$ cells which are more predominant and more likely involved in the pathophysiology of COPD.[71,72]

The mucosal layers of the airways contain local lymphoid follicles that consists of a core B lymphocytes surrounded by T cells and it has been suggested that the antigens are presented to the T cells in these lymphoid nodes resulting in clonal expansion of $CD4^+$ cells and to larger extent $CD8^+$ cells.[73] The $CD8^+$ and $CD4^+$ cells are fully activated in the lungs of COPD with the increased expression of inflammatory mediators such as CXCR3 with parallel strong epithelial expression of its ligand Interferon Gamma (IFN-γ) Inducible Protein 10 (IP-10), which is a powerful chemoattractant of the CD8 lymphocytes.[74,75] IFN-γ has been implicated in driving and maintaining T cell responses and promotes an immune inflammation with neutrophils and macrophages. The IFN-γ stimulated $CD8^+$ cells release further destructive enzymes, such as perforin and granzyme B, which have the ability to induce apoptosis of the alveolar epithelial cells.[76-78] The $CD8^+$ lymphocytes also produce battery of other cytokines such as IFN-γ, IL2, IP-10, monokine induced by IFN-γ (CXCL9), IFN-γ inducible T cell alfa chemoattractant (CXCL11) and IL-4, which are known to stimulate other inflammatory cells and mediators in COPD (Fig. 79.6).[70,75,77]

Intriguingly, an antigenic mechanism is required to stimulate the T cell inflammatory response. This inflammatory response appears in mild COPD and increases markedly with increasing disease severity and persists even after the triggers, such as air pollution or tobacco smoke, are removed. This self perpetuation of the adaptive immune system confers further understanding as it may explain the persistence of inflammation in the lungs of COPD patient. It is possible that the inflammatory and oxidative stress injury can

create endogenous autoantigens in the lungs augmenting continued CD4/CD8 response in the lungs.[70] There are also antigens in the tobacco smoke, which may also induce the response. Another possibility is that this chronic immune response is actuated, or at least continued, by chronic infectious processes of the respiratory tract often seen in the patients with severe disease, in which there is increased colonization of the lower airways. These infections could either costimulate or mimic as an antigen and provide a persisting antigenic stimulus that maintain the inflammatory processes.[79-82] The association between recurrent childhood viral infections and the development of COPD in adult life, indicate that viruses and bacteria recruit lymphocytes into the lungs as a part of the adaptive immunity (Fig. 79.7).

Interestingly, in the chronic cigarette smokers who do not develop COPD, the autoantigens generated by the oxidative stress and toxins may also induce the lymphocytic inflammation. But this induction is controlled by the subset of another $CD4^+$ cells, collectively known as regulatory T cells, which are capable of suppressing autoreactive lymphocytes through the secretion of inhibitory mediators such as IL-10 or direct cell–to-cell contact.[83] In COPD, there is a greater increase in $CD8^+$ cells than the T regulatory cells and there is also evidence that the number of these cells may be reduced, thereby further enhancing the autoimmune processes.[83] Furthermore, inflammatory ligands of CXCR3, which have been shown to be increased in the lymphocytes of COPD lungs have also shown to increase the expression of MMP-12 in the alveolar macrophages, thereby providing a direct link between T cells and alveolar destruction.[84]

The mounting evidence implicating T cells as important components of COPD inflammation is overwhelming. The understanding that the COPD inflammation is most likely driven by antigen has tremendous therapeutic interest. Currently, there is search of molecules that could inhibit receptors, such as CXCR3 and block the trafficking of Th1 and Tc1 cells into the lungs.[70]

Role of Inflammatory Mediators in COPD

The composition of inflammatory mediators involved in COPD pathogenesis has varied and include cytokines such as TNFα, IL-6 and IL-5; chemokines such as GRO alfa, MCP-1, MIG (IP-10), LTB4 and IL-8; oxidation products such as 8-isoprostane; hormones such as leptin; and enzymes such as MMPs, serine proteinases and neutrophil elastases and many more.[85-91] Amongst these IL-8 is primarily released by stimulated macrophages, epithelial cells, endothelial cells and neutrophils and is one of the most abundant inflammatory mediators present in COPD. It also increased during COPD exacerbations rendering it to be an important inflammatory mediator involved in accelerated decline in the lung volumes.[92-96] The systemic IL-8 has also shown to be related to increase peripheral muscle weakness in COPD, which is one of the most common systemic manifestations of the pulmonary disorder.[97] IL-8 has shown to increase the mRNA abundance of mucin genes in *in vitro* experiments. Upregulation of airway mucin genes by inflammatory/immune response mediators is one of the major contributors to mucin overproduction in COPD.[98,99]

The secretion of IL-8 is augmented by the triggering of IL-8 genes in macrophages, epithelial cells, endothelial cells and neutrophils in the lungs by stimulants such as cigarette smoke, air pollutants, free oxidant radicals and M3 receptor agonists.[100] The secreted IL-8 binds with receptors such as CXCR 1 and CXCR2, and also the toll receptors, present on the target cells.[101-104] The primary function of IL-8 is to induce cellular chemotaxis of neutrophils. However, in addition IL-8 also induces series of other cellular-physiological responses required for its migration and its target function phagocytosis like increase of intracellular Ca^{2+}, exocytosis of proteinases and generation of free oxidant radicals, degranulation of neutrophils and release of neutrophil elastase. IL-8 is also known to activate macrophages,[105] CD-8 lymphocytes, endothelial cells[106] and mast cells.

These diverse properties of IL-8 have made it an important target for COPD therapy. Notably, a recent preliminary clinical trial has shown that treating COPD subjects with the monoclonal antibody against lL-8 can improve dyspnea in COPD patients, but it fails to improve lung functions.[107] This means that targeting IL-8 perhaps may not be enough to control COPD inflammatory ravage. Moreover, therapies such as these could also affect the activity of neutrophils, which are important defense cells required for innate immunity that could lead to the development of infections in the respiratory tract.

TNF-α is another inflammatory mediator with an important role in COPD pathogenesis. Sputum and BAL samples from the COPD subject have shown to increase in the presence of TNF-α in the airways and lung parenchyma. The increased number of macrophages in COPD are a potential significant source of TNF-α.[89] The physiological outcomes of COPD inflammation, such as increasing airflow obstruction, hypercapnia[108] and hypoxemia[109] are shown to be associated with an enhanced TNF-α response in COPD. TNF-α enhances neutrophil chemotaxis and migration by inducing the expression of chemokine IL-8 and by up-regulation of endothelial adhesion molecule.[94,95] It also induces apoptosis in the macrophages[110] and is the major systemic inflammatory mediator that causes the weight loss and nutritional depletion seen in COPD.[91,111]

Increased levels of TNF-α have also been detected in the sputum of subjects with exacerbations of COPD.[112] The increased number of macrophages in COPD is a potential significant source of TNF-α. The levels of TNF-α increase during exacerbations and exercise.[112,113] TNF-α has been also shown to be associated with increased leptin levels in the blood, which is a cytokine that regulates nutrition, especially during COPD exacerbations indicating TNF-α may lead to changes in nutritional parameters and body weight in the course of the disease.[91] Further, genetic studies have also indicated that the range of COPD phenotypes may be driven by specific underlying genetic polymorphism occurring in the TNF-α gene.[114]

With such a diversified role in the pathogenesis of COPD, the assumption of negating the affects of TNF-α with conventional TNF-α antagonist seems to be a thought provoking strategy to manage COPD. However in a randomized, double-blind, placebo controlled, phase II clinical trial, infliximab did not show any significant clinical benefit in COPD patients,[115] indicating, that targeting one specific inflammatory mediator may not be enough to control COPD inflammation.

Leukotriene B_4 (LTB_4) is another inflammatory mediator that has been implicated as the major chemoattractant responsible for neutrophil recruitment and activation in COPD. LTB_4 seems to be the prominent chemotactic factor in patients with the most severe COPD and during acute exacerbations. Its major source is probably the alveolar macrophage and it is assumed that the recruitment of neutrophils could further amplify the effect.[87] The elastase could stimulate the macrophages to release more LTB_4, resulting in further neutrophils recruitment.[87] In addition, LTB_4 also recruits CD8 T cells to the sites of inflammation.[116] LTB_4 receptors are further up-regulated on the macrophages and neutrophils of COPD patients. Antagonism of LTB_4 receptors is currently being considered as a mode for treating COPD.[117]

IL-6 is an inflammatory mediator, which has been frequently associated with systemic comorbidities in COPD.[118,119] This cytokine has been found in great abundance in both systemic circulation and airways of COPD subjects and its enhanced expression has been related to the symptoms of breathlessness, skeletal muscle weakness, insulin resistance, pulmonary hypertension, cardiovascular morbidity and most significantly exacerbations. [118,119] IL-6 has shown to increase fibrinogen levels and thrombocytes in systemic circulation of the COPD subjects, which increases the risk of ischemic heart disease and myocardial infarction in these patients.[119] Remarkably, myocardial infarction is the primary cause of mortality in the COPD patients and IL-6 can be attributed to this. Pulmonary hypertension that occurs secondary to COPD may also be accounted to IL-6. This interleukin has been shown to induce pulmonary artery remodeling in all severities of COPD primarily due to hypoxic stimuli, which is known to cause presser affects on pulmonary vasculature and induces an over expression of the IL-6 genes. IL-6 further potentates pulmonary pressure response to hypoxia and promotes micro-arteriole thrombosis in the lung.[120]

Muscarinic Receptors

Muscarinic receptors have also been shown to play an important role in the pathophysiology of various airway inflammatory diseases, including COPD. Airway smooth muscle expresses abundant muscarinic M_2 and M_3 receptors, roughly in a 4:1 ratio.[121] M_2 receptor is an inhibitory receptor, while M_3 is a primary receptor subtype responsible for bronchial and tracheal smooth muscle contraction. In COPD, the cholinergic activity and muscarinic responses are enhanced and this is due to increased activity of M_3 receptor, although, their numbers do not increase in the airways.[121-125]

The M_3 receptors constrict smooth muscles primarily by modulating calcium kinetics in the muscle cell. Stimulation of M_3 receptors activates phospholipase-C (PLC) Inositol 1,4, 5-trisphosphate (IP_3)[121] and CD 38 - cyclic ADP ribose (cADPr) pathways to induce the movement of calcium out of sarcoplasmic reticulum into cystol for the activation of myosin-actin contractile apparatus.[126-130] M_3 receptor stimulation also enhances the sensitivity of calcium ion in the cell by inhibiting myosin light chain phosphatase (MLCP) through pathways such as phosphoinositide-derived diacylglycerol (DAG)-protein kinase C (PKC)-CPI-17 and RhoA-Rho kinase pathway.[131-144] An increased expression in these molecules has been shown in the presence of inflammatory mediators such as those seen in COPD and cigarette smokers.

In addition, there is a vagal neuronal mechanism, which is modulated in COPD. The inflammation and environmental insults damage the epithelial cells of the airways and expose the ubiquitously present C-afferent nerve fibers lying in the subepithelial region. These fibers when stimulated, due to noxious stimuli and inflammation, transmit messages to the central nervous system, which reacts by increasing the acetylcholine vagal transmission to the bronchi. The acetylcholine acts on both the active muscarinic receptors, such as M_1 and M_3, and inhibitory receptor M_2.[145-152] But, due to underlying inflammation the inhibitory affects of M_2 receptors are dysfunctional in COPD, leaving only the M_3 and M_1 receptors to act on the airway smooth muscles. This results in bronchoconstriction, mucus hypersecretion and cough.[153-157] The cholinergic-receptor stimulation has shown to act synergistically with growth factors to activate mucus cell activation and goblet cell hypertrophy, which is a pathological hallmark of various airway inflammatory diseases such as COPD.[158-161] This indicates that blocking these receptors could have far reaching bronchodilatory effects than the other bronchodilators acting through different mechanisms. Clinical experience with antimuscarinic receptors has indeed supported this argument.

Muscarinic receptors are also known to cause mesenchymal cell proliferation, differentiation and pulmonary vascular remodeling. More recently the increased expression of the M_3 receptor has been identified on macrophages, neutrophils and lymphocytes of COPD patients.[162-165] There is also an evidence of increased acetylcholine induced neutrophilic chemotactic activity in COPD (Fig. 79.8).[166,167] Very recently it has been shown that M_3 receptors augment cigarette smoke induced IL-8 secretion from the smooth muscle cells, and that selective muscarinic antagonists abrogate these effects.[168,169] Thus, anticholinergic therapy can potentially achieve far reaching significant controller effects in COPD that extends its capacity as medication to promote bronchodilatation.

Fig. 79.8: Role of muscarinic receptors in pathogenesis of COPD

Role of Oxidative Stress in COPD

There is now overwhelming evidence for the presence of increased oxidative stress in patients with COPD. Oxidative stress has a very significant role in every stage of the pathogenesis in COPD. Increased oxidative stress in the airspaces can initiate a number of early inflammatory events in the lungs. The free oxidant radicals in the lungs and systemic circulation arise from the sources of air pollutants such as cigarette smoke and biomass fuel, and also inflammatory cells such as neutrophils and macrophages.[170]

Amongst the complex mixture of over 4,700 chemical compounds present in the cigarette smoke, free radicals and other oxidants account for the major deleterious effects on the respiratory system. It has been estimated that cigarette smoke contains approximately 10^{15} oxygen radicals per puff, primarily of the alkyl and peroxyl types.[170] The other important compounds present in cigarette smoke include nitrous oxide and semiquinone, which are also capable of producing reactive oxygen species such as superoxide anion (O_2^-), peroxynitrite, alkyl peroxynitrites and hydrogen peroxides.[171] On the other hand, the oxidant burden of biomass fuel has not been yet demonstrated, but considering inhaling the smoke released from burning biomass without the intervention of filter could be a much higher source of reactive oxygen compounds than cigarette smoke.

The epithelial lining fluid and mucus are the first line of defense in the lungs against inhaled oxidants by quenching the short-lived radicals in the cigarette smoke.[172] However, cigarette smoke condensate, which forms in the epithelial lining fluid, may continue to produce reactive oxygen species for a considerable period in patients with COPD, as part its pathogenesis.[173,174] Reactive oxygen species are also released from activated inflammatory leukocytes, such as neutrophils and macrophages,[42,175-181] which are known to present in increased numbers in the lungs of cigarette smokers. The inflammatory mediators released by these cells permanently switch on the oxidative stress mechanisms, providing a continuous source of free oxidant radicals, which not only confine to the lungs, but also spill into the systemic circulation and affect other body organs with particular predilection to the heart and skeletal muscles.[20]

A series of physiological and pathological changes present in COPD have been attributed to oxidative stress, which include the oxidative inactivation of antiproteases and surfactants, mucus hypersecretion, membrane lipid peroxidation, alveolar epithelial injury, remodeling of extracellular matrix and apoptosis. Reactive Oxygen Species (ROS) have been shown to reduce the synthesis of elastin and collagen and also fragmenting these skeletal proteins. ROS affects the structure of matrix proteins such as hyaluronate and proteoglycans and reduces the viscosity of the extracellular matrix for easy movement of inflammatory cells. Moreover, oxidative stress reacts with the membrane phospholipids present in the airway epithelial cells and activates the arachidonic acid in the cell membranes to release prostaglandins and leukotrienes, which are potent inflammatory agents. Injury to the epithelium may be an important early event following exposure to cigarette smoke, and is shown by an increase in airspace epithelial permeability and this has been shown to be strongly associated with increased amount of free oxidant radicals in the airways.[170]

Oxidative stress also activates other cellular systems that increase the production of inflammatory mediators such as IL-8, IL-1 and TNF-α. It also enhances the aging process by down regulating various anti-aging molecules such as Nrf2, sirtuin, histone deacetylase (HDAC) and oxidative protein, and also activates processes that are implicated in cell senescence and Deoxyribonucleic Acid (DNA) damage. Furthermore steroid resistance of COPD inflammation has been implicated to be caused by increased oxidative stress.[182] Oxidative stress reduces steroid responsiveness via a reduction in HDAC2 activity and expression (Fig. 79.9).[182]

Airways are always exposed to various ambient pollutants, which are inhaled during respiration, that generate oxidative stress inside the airways. The airways are protected from this ongoing oxidative stress by a series of antioxidants, which are found ubiquitously in the respiratory tract lining fluid throughout the respiratory tract. These antioxidants generally present in the fluid lining the airways are cysteine residues such as mucin and glutathione, uric acid, albumin, vitamin E and vitamin C.[183-188] The reactive oxidant species enhance the secretions of mucin[189] and glutathione in the respiratory lining fluid to counteract the oxidant load, but in diseases like COPD, this increase may not be sufficient to deal with excessive oxidant burden seen in this disease either due to is depletion of the antioxidants or reduced production.[170] Therefore, an improvement in the antioxidant capacity in COPD patients is an interesting therapeutic approach. Currently there is no effective antioxidant therapy, which can effectively thwart the oxidative stress in the lungs of COPD patient. However, N-acetyl-cysteine (NAC), a precursor of glutathione, which is a very powerful and ubiquitously distributed antioxidant has met with varying success with more positive results in higher doses.[182]

Other interesting antioxidants, such as dietary polyphenol (curcumin-diferuloylmethane, a principal component of turmeric); resveratrol (a flavonoid found in red wine); green tea (theophylline and epigallocatechin-3-gallate); ergothioneine (xanthine and peroxynitrite inhibitor); quercetin; erdosteine and carbocysteine lysine salt; spin traps such as α-phenyl-N-tert-butyl nitrone; a catalytic antioxidant (ECSOD mimetic); manganese (III) meso-tetrakis (N,N′-diethyl-1,3-imidazolium-2-yl) porphyrin (AEOL 10150 and AEOL 10113); and a superoxide dismutase mimetic M40419 have also been reported to inhibit cigarette smoke-induced inflammatory responses *in vivo*.[182] Since a variety of oxidants, free radicals and aldehydes are implicated in the pathogenesis of COPD, it is possible that the therapeutic administration of multiple antioxidants will likely be effective in the treatment of COPD.

COPD: A Disease of Accelerated Aging[182]

The link between aging and the pathogenesis of COPD has been elucidated in numerous studies. Senescence is a complex outcome of both intrinsic and environmental factors, especially oxidative stress, and therefore, the role of pollutants, such as cigarette smoke and indoor air pollution are key factors linking aging lung to COPD. Although, at the molecular level there are numerous similarities between aging and COPD, the molecular mechanisms have not yet been fully explored.

As the age increases, there is a indolent decline in lung function with airways showing physiological airway obstruction ($FEV_1/FVC<70\%$) along with emphysema even in the normal healthy elderly population who may have never smoked in their life. These observations indicate that the number of neutrophils in the lower respiratory tract of healthy elderly individuals is likely increased, and there is increased release of neutrophil elastase, which could contribute to the loss of elastic recoil and of elastin fibers in the aging lung, which in turn would reduce interdependence between the airways and parenchymal structures, thus contributing to the deterioration of lung function.[182] Intriguingly, in COPD all these changes occur, but at much earlier age. Glucocorticoid sensitivity is reduced during aging as well as in COPD.[190-192]

The oxidative stress also drives proinflammatory transcription factors such as NFêB to switch on multiple inflammatory genes responsible for the expression of various inflammatory mediators and forms an important aspect of normative aging process. This mechanism is accelerated in COPD, especially in the lungs, adding to the body of evidence that COPD is a disease of accelerated aging of the lungs.

COPD is disease of accelerated lung aging

Fig. 79.10: Role of oxidative stress and accelerated aging process in COPD

The molecular transitions, which are responsible for aging, are such that the growing oxidative stress due to accumulating free reactive oxygen species alters the genetic machinery by damaging the DNA and shortening the telomere. A telomere is a region of DNA at the end of a chromosome, which protects the end of the chromosome from deterioration and shortening with each round of cell division. This mechanism limits the proliferation of human cells to a finite number of cell divisions by inducing replicative senescence, differentiation or apoptosis. Eventually, the cells with shorter telomeres can no longer replicate and taken over time the signs of aging start showing up. Oxidative stress, not only greatly accelerates telomere shortening in cells, but also causes somatic mutations in DNA, thereby causing the DNA damage, and COPD is a disease in which oxidative stress is amplified by several folds. Telomere length has been demonstrated to be significantly shorter in patients with emphysema than in asymptomatic nonsmokers in alveolar type II cells and endothelial cells, peripheral blood mononuclear cells and fibroblast (Fig. 79.10).[182]

Deficiency of several anti-aging molecules such as sirtuins, klotho, Senescence Marker Protein-30 (SMP30), HDAC and Nuclear Factor Erythroid 2-Related Factor 2 (Nrf2); the molecules responsible for DNA repair, such as DNA-dependent protein kinase (DNA-PK) and Ku86 (or Ku80), have shown to cause emphysematous changes in the lungs and various other senility related changes in animal models. Increasing oxidative stress, a regular outcome of aging, decreases these molecules in various organs exposing them to aging changes. Currently these molecules form very important therapeutic targets for research in various chronic diseases associated with aging such as COPD.[193-199]

COPD is a Disease of Systemic Inflammation

Chronic obstructive pulmonary disease has classically been considered to be an intrathoracic condition characterized by poorly reversible airway obstruction. However, COPD has been recently recognized as a multicomponent disorder, associated with systemic inflammation and extrapulmonary manifestations. It has now been well documented that the inflammation that develops in the patient, does not confine to the lungs, but spills into the systemic circulation through the pulmonary vessels and predisposes almost every organ system in the body with particular predilection to the heart, as the heart is the first organ that receives all the blood from the pulmonary vasculature.[200-212]

Fig. 79.11: Systemic effects of COPD inflammation

There is always a persistent, low-grade systemic inflammatory response present in part of COPD patients. Various studies have shown enhanced levels of acute phase proteins like C-Reactive Protein (CRP)[213,214] and proinflammatory cytokines such as TNF-α[215] and IL-6[216,217] in many COPD patients. Moreover, there has been a consistent strong association between reduced lung function and systemic inflammation. Even increased polymorphisms have been shown in the inflammatory genes and there is increasing interest in identifying a haplotype of inflammatory genes, which predisposes to systemic manifestation of COPD.[218]

These inflammatory makers along with persistent hypoxia increase the basal metabolism in the body leading to catabolic changes such as reduced muscle mass, wasting of skeletal muscles and diaphragmatic weakness. Notably, interventions such as regular exercise and physiotherapy have been shown to reduce systemic inflammation. Further the systemic inflammation also increases oxidative stress in various other organs. COPD is associated with chronic heart failure in more than 20% of patients and myocardial infarction is by large the commonest cause of mortality in all grades of severity COPD. Up to 70% of COPD have underlying osteoporosis.[202,203] There has also been a strong association between depression and COPD. There is emerging evidence indicating insulin resistance in some COPD patients due to systemic inflammation and recently an association with diabetes and COPD has been demonstrated. COPD has also been related to metabolic syndrome as it predisposes patients to increased cardiovascular morbidity and diabetes mellitus (Fig. 79.11).[200]

There is increasing interest in reducing systemic inflammation with medications like low-dose statins,[219] antioxidants[220] and steroids[221] for the chronic management of COPD. Some retrospective observations indicate that such concomitant medications have the potential to increase survival and morbidity in COPD patients.

Pulmonary Function Testing in Chronic Obstructive Pulmonary Disease

Tavpritesh Sethi, Anurag Agrawal

HISTORY AND EVOLUTION

The role of Pulmonary Function Testing (PFT) in diagnosis and management of Chronic Obstructive Pulmonary Disease (COPD) has evolved over time. While accurate descriptions of the diseases grouped together under COPD predate any formal definitions,[1] the recognition of progressive respiratory symptoms and illnesses arising after exposure to noxious stimuli, especially cigarette smoke came much later in the mid 20th century. These illnesses were formerly known by multiple labels, of which two, namely chronic bronchitis and emphysema, were officially endorsed by the American Thoracic Society in 1962.

"Chronic bronchitis" was defined as a cough productive of sputum for at least three months of two consecutive years. Emphysema was defined in anatomic terms of enlarged alveolar spaces due to the destruction of alveolar walls. Neither definition encompassed any physiologic considerations. The term "COPD" encompassing both chronic bronchitis and emphysema is considered to have originated soon after.[1] In this era, the definition of COPD was mostly in clinical or structural terms and the disease was well established by the time a diagnosis was made. While the scientific and technical basis of PFTs, including all current methods was already well established by this time due to seminal work by stalwarts of the field, such as DuBois, Hyatt and Mead, the full recognition of the clinical utility of these tests in COPD came much later.

The 1959 Ciba symposium on "terminology, definitions and classification of chronic pulmonary emphysema and related conditions" presciently stated that the standardized collection of functional, clinical and pathological data may lead to the development of specific diagnostic criterion.[2] Forced expiratory tests of "ventilatory function," identical to modern spirometry and tests of "alveolar-capillary and circulatory function," such as arterial blood gases and cardiopulmonary exercise testing, were recommended as essential tests. Tests of lung compliance and resistance by the use of an esophageal balloon and a whole body plethysmograph (body box) were recommended as supplemental tests, amongst others such as gas diffusion and nitrogen washout. Over the next few decades, alterations in such measures of physiologic function were correlated to clinicopathological data and it became possible to reliably distinguish between the common lung diseases.

With the emergence of computed tomography as a preferred test to study structural lung diseases, such as emphysema, pulmonary fibrosis, etc. relatively simple and widely available tests like spirometry that primarily measure expiratory airflow limitation in Obstructive Airway Disease (OAD), supplanted more complex methods. Over time, this has led to new definitions of COPD in which previous distinctions are done away with and the disease is simply defined in functional terms, as predicted in the 1959 Ciba symposium. The most recent guidelines from Global Obstructive Lung Disease (GOLD) initiative of World Health Organization/ National Heart Lung and Blood Institute state that COPD is a disease state characterized by airflow limitation that is not fully reversible.[3] The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles and gases. The GOLD initiative revolutionized the definition of COPD by entirely basing the diagnosis of COPD upon the measurement of airflow limitation. It also emphasized the need to educate primary care and general practitioners, and to promote objective criterion.

Today, pulmonary function testing to evaluate airflow limitation is by definition necessary to diagnose COPD and also contributes immensely to its management. The various approaches and their relative merits are summarized in the following sections. To conform to the GOLD definition of COPD, pulmonary function testing needs to be done initially to look for airflow limitation, followed by the response to bronchodilators to look for reversibility and finally, multiple times thereafter to call the obstruction as persistent or progressive, these being key features of COPD. However, this does not mean that the GOLD definition is all inclusive and there is scope to incorporate factors such as dyspnea, which correlates well with subjective disability and Quality of Life (QoL); as well as other assessment of functional capacity like the six-minute walk test.

THE CLINICAL NEED FOR PULMONARY FUNCTION TESTS

Early Diagnosis

The need for pulmonary function testing in diagnosing COPD is not just a question of semantics and academic distinctions. Chronic obstructive pulmonary disease has a relatively silent stage where measurable airflow limitation exists despite a paucity of symptoms. In this phase, smoking cessation, the most effective intervention, can arrest the progression of COPD. Therapeutic options in advanced stages are poor and cannot reverse the disease. In a large study conducted in the United States,[4] it was seen that most patients with spirometric abnormalities diagnostic of COPD or other obstructive disease never had their conditions diagnosed, nor were they receiving systematic therapy. Similar studies in the United Kingdom[5] and Canada[6] show strikingly similar figures with about 67% of patients who visited primary care for any reason having undiagnosed obstructive disease.[6] Importantly, poor lung function was strongly associated with adverse outcomes, which could have been avoided or delayed by early diagnosis and treatment. Thus, clinicians must become aware of the fact that obstructive airway disease is no longer an exclusively clinical diagnosis and there is an unmet need for better detection early, because the true prevalence of COPD is much higher than it seems. It can be very conservatively estimated that in our own practices, in the absence of lung function testing, about half of the COPD cases might be missed.

Management

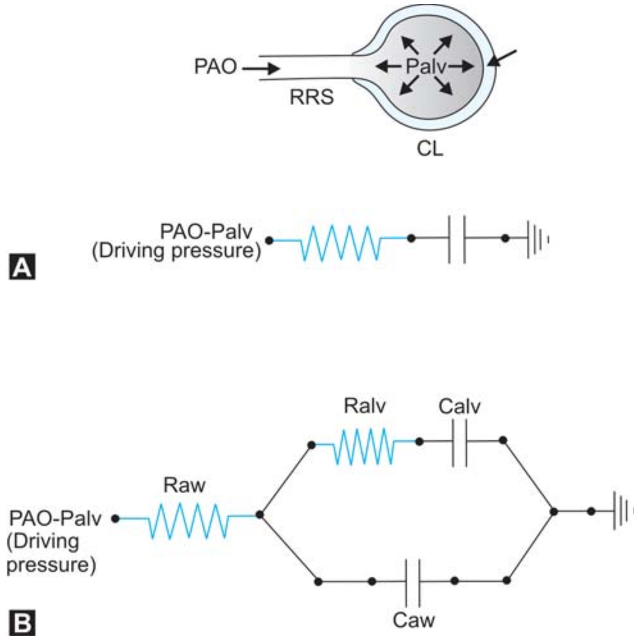
Optimal management of lung diseases, including COPD, requires objective assessment of lung function in addition to the subjective assessments of well-being. In addition to guide bronchodilator therapy, subsets of COPD patients identifiable by functional testing, may benefit from treatment with inhaled corticosteroids.[7] Some of these may have an asthmatic component characterized by partial reversibility to bronchodilators and increased exhaled nitric oxide. Other important uses for pulmonary function testing in routine practice include preoperative risk assessment and determination of suitability for pulmonary surgeries.[8,9]

PHYSIOLOGICAL PRINCIPLES

It may be pertinent to briefly review the physiology of the respiratory defect in COPD before discussing the findings and interpretation of the investigations. Airflow limitation, which defines COPD, refers to a reduced maximal expiratory flow of air despite normal respiratory effort. While a full review of the mechanical properties of the lung relating to the flow of air during breathing are beyond the scope of this chapter, a brief introduction is provided in a simple mechanical model of the lung.[10,11] It can be seen that expiratory flow of air can be diminished by increased resistance of the conducting airway, reduced driving pressure, or both (Figs 80.1A and B). Key concepts of how these mechanisms relate to COPD are discussed further.

Airway Resistance in COPD

The major mechanisms of increased resistance in COPD are narrowing, dynamic closure and occlusion of airways. Narrowing of airways is due to a multitude of causes such as thickened and inflammed mucosa, hypertrophied smooth muscle, and loss of expansile stretching effects of lung parenchyma. Airway closure is a physiological mechanism by which further exhalation at lower limits of lung volumes (Residual Volume, RV) is prevented by apposition of airway walls. This is exaggerated in narrowed and inflammed COPD airways, sometimes to the extent that it can be seen at tidal volumes of breathing. This pathological increase in RV is compensated by hyperinflation, which is the compensatory mechanism of the lung to “pull open” the



Figs 80.1A and B: A simplified model of the lung showing airflow to the alveoli as a function of airway resistance, driving pressure and lung compliance.
PAO: Pressure at the airway opening; Palv: Alveolar Pressure; PPL: Pleural Pressure.

airways. This has adverse mechanical consequences leading to increased work of breathing and ineffectiveness of respiratory muscles, as discussed in the next section.

The third mechanism of airflow limitation is the occlusion of the airways, most commonly by mucus plugs. This is distinct from the increased mucus production in the large airways, which while causing cough, does not cause airway occlusion. Here, it is important to realize that the bronchial tree is a parallel arrangement of resistances and hence, the increase in resistance is much greater with a homogenous narrowing, even of a smaller degree than a localized complete obstruction. This is determined by the law of parallel resistances, $1/R = 1/R_1 + 1/R_2 + \ldots + 1/R_n$; such that homogeneous reduction of all airway diameters by half would lead to 16-fold increase in reductions (fourth power) while equivalent complete obstruction in terms of area, would lead to only four-fold increase in resistance. This translates conceptually to the fact that the total resistance in a parallel arrangement is lower than the lowest resistance, hence the lesser rise in resistance with a segmental collapse or a localized obstruction than with a total obstruction in a portion of the airways. Another fact to consider is that in normal lungs the cross-sectional area increases markedly while moving through the progressively higher generations of airways (Weibel's Trumpet Model).[12] Thus the small airways with their maximal contribution to area contribute least to the resistance of the airways. Since, these are the initial sites of pathology, techniques that permit detection of small airway disease hold promise in COPD diagnosis.

Expiratory Driving Pressures in COPD

In addition to obstruction, especially with emphysema as the predominant pathology, there is destruction of the lung tissue leading to a decrease in elasticity and loss of the supporting structures around airways and the alveolar walls. The loss of elastic recoil leads to reduced driving pressures for any given volume during expiratory flow, and higher volumes for a given transpulmonary pressure than the normal lung. The static expiratory pressure-volume curves (Fig. 80.2) show this as a marked deviation from the normal slope of the pressure volume relationship with a higher Total Lung Capacity Ratio (TLC), Functional Residual Capacity (FRC) and RV. All the above changes in COPD are attended by mechanical consequences, such as flattening of the diaphragm and abnormal inspiratory muscle action angles on the ribcage. These are the primary causes for the feeling of breathlessness in COPD patients. The loss of parenchymal support also implies that airways are more prone to collapse.

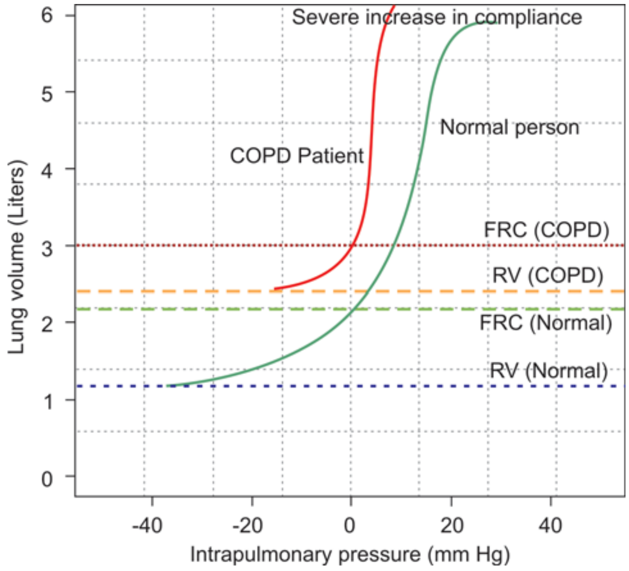


Fig. 80.2: Pressure-volume curve for the respiratory system of a healthy subject and a COPD patient. The TLC, RV and FRC, all are increased in COPD.

The reduced driving pressures, hyperinflation and increased propensity to collapse are characteristic of COPD in contrast to increased airway resistance which is also seen in asthma. Together, these result in expiratory airflow limitation as discussed below.

Expiratory Airflow Limitation: Principles and Pitfalls

During forced exhalation, there is an effort-dependent phase, where the driving pressure is dependent upon the effort followed by an effort independent phase where the elastic recoil of the lung determines the driving pressure. It is important to note that in the effort independent phase, the resistive segment is not the entire airway but only the region proximal to the pressure equalization point. This point is referred to as the choke point, simplistically shown as collapse of the airway, but more accurately the point where local flow velocity reaches the local speed of wave propagation. Figure 80.3 shows the common indices related to expiratory flow limitation during a forced exhalation maneuver. Notably, these correlate to the resistance of airways to airflow, but are only an indirect approximation since they are influenced by: Effort; lung recoil; location of choke point; and resistance of a variable segment defined by the location of choke point(s).

Other methods to indirectly assess airflow limitation include direct measurements of the resistance of the airways [Whole Body Plethysmography (WBP), body box] or the respiratory system [Impulse Oscillometry System (IOS) or Forced Oscillation Technique (FOT)].[13] These are substantially different from spirometry, which directly measures expiratory airflow limitation during a

Figs 80.3A to D: Common indices of expiratory airflow limitation (during a forced inhalation maneuver)

forced exhalation maneuver. In WBP, the relationship of measured changes in airflow (dV') to calculated changes in alveolar pressure (dPalv) during breathing is used to estimate either airway resistance (Raw) or specific airway resistance [SRaw; SRaw = Thoracic gas volume (TGV) x Raw]. Since alveolar pressure changes cannot be directly measured, the patient breathes in a closed body box such that, using Boyle's law, they can be estimated (dPalv = PdV/V, where P is BTPS corrected atmospheric pressure and V is TGV). In contrast, IOS or FOT rely upon the additional airflow (V') induced by applied pressure signal (P).

The use of suitable impulses (IOS) or pseudorandom noise (PRN-FOT), allows determination of respiratory system impedance [Zrs and its frequency dependence (Zrs{f} = P{f}/V'{f}/)]. Zrs being a complex parameter is further split into a resistive component (Rrs) and a reactive component (Xrs). The reactive component comprises of inertive behavior of air that resists acceleration and an opposing elastic behavior of lung (mostly parenchyma) that stores energy during volume expansion. Importantly, the elastic component is not the inverse of static compliance but reflects nondissipative energy storing properties of the lungs. Diseased stiff lungs that have a low compliance have reduced ability to store and return energy. In many ways, this is analogous to an electrical circuit. Advanced readers with interest in IOS can find more detailed information elsewhere.[14]

CLINICAL APPLICATIONS

Spirometry

Spirometry remains the cornerstone of diagnosis in COPD, but care must be exercised in following the procedure to the highest applicable standards.[15-19] Since, it measures flow limitation during a forced expiratory maneuver, the key aspects are adequacy of the maneuver, accurate measurement of flow, appropriate use of normal reference values, and last but not least—repetition. Quality assurance guidelines based on the standards defined by GOLD, are presented below, divided into test preparation, performance and evaluation.

Preparation

- Spirometers should be calibrated on a regular basis, preferably weekly for machines that measure volume (bellows) and daily for machines that measure flow (differential pressure pneumotachograph, turbine, ultrasonic). Calibration is done by using a gas syringe that pushes known volume of air through the device at a representative flow rate. Some technologies, such as pneumotachographs, require more careful attention to calibration than others. Changes in ambient temperature may require recalibration.
- The personnel conducting the test should be thoroughly trained for conducting spirometry. Since spirometers have individual quirks based on the technology used for volume/flow detection, the training must be relevant to the actual instrument in use. Except in rare circumstances, most modern spirometers provide equivalent data and are often pre-certified to comply with international guidelines. While a full discussion on choosing spirometers is beyond the scope of the current test, there is no such thing as "the best spirometer" and the choice depends upon the intended application.
- Spirometers that provide visualization of the flow-volume loop should be used. Else, the equipment should have the capability to recognize a "bad-test," such as an inadequate expiration and prompt the possible reason for the error. It is preferable to use spirometers that conform to digital data standards that are portable across systems for easy collation of data.

Performance

- Accurate and reproducible spirometry requires careful attention to the detail. The exhalation should be forceful, fast and complete. The posture of the individual should be straight to maximize the force developed by the chest and abdominal wall muscles.
- At least three reproducible volume-time curves are necessary and at least two out of the three Forced Expiratory Volume in One Second (FEV_1) values should be within 5% or 100 ml of each other (whichever is greater). The best measurement is selected for comparison against the predicted values.
- The expiratory volume-time curves should be smooth and free from irregularities. This is particularly troublesome in individuals with cough which creates irregular flows during the test. Ironically, the maneuver itself has a tendency to precipitate cough and airway closure in persons with airway disease.
- The exhalation should begin from a full inspiration and should continue until it reaches a plateau. This might take anywhere between 6 and 15 seconds or even longer in severely diseased individuals.
- FEV_1/ Forced Vital Capacity (FVC) ratio should be selected from the technically acceptable curve with the largest sum of FVC and FEV_1.

- The above-mentioned procedure is repeated after a bronchodilator has been given to characterize the reversibility of the obstruction.

Evaluation

- The results are compared with the predicted normal values of FEV$_1$ and FVC for that particular age, sex, height and race.
- The ratio of FEV$_1$ to FVC is termed as Forced Expiratory Ratio (FER). The postbronchodilator FER of less tha 0.7, along with FEV$_1$ less than 80% predicted value confirms airflow limitation that is not fully reversible.
- The predicted values should be appropriate for the population under study. In India, we should use local reference values rather than standard western standards that often come with the equipment.[20] However, the lack of such predictive values in the elderly creates a risk of over-diagnosing COPD due to the fall in normal lung function with age. GOLD mentions this as one of the urgent step to be taken for proper diagnosis.
- The measurements should be serially repeated over time to assess the progression of airflow limitation. Typically COPD is defined as a progressive disorder without reversibility of airflow limitation.

Typical shapes of flow volume loops from spirometry tests (Fig. 80.4) can help to identify the pattern and site of airway obstruction.

Spirometric Classification of Severity

In this chapter, we conform to the GOLD guidelines update 2009 for diagnosing and classifying COPD.[3] While these guidelines seem to result in the increased risk of false negatives in young and false positive in elderly subjects, compared to alternative recommendations from American Thoracic Society and European Respiratory Societies; they serve as important global standards. The spirometric classification stages the disease into four stages on the basis of severity. The initial diagnosis relies on the postbronchodilator spirometric cut-point of FEV$_1$/FVC as less than 0.7. These cut-off points are chosen for the sake of simplicity and have not been validated clinically, but support for taking FEV1/FVC less than 0.7 as a diagnostic criterion comes from a study on a random sample which shows that in healthy people of all ages, the ratio was more than 0.7. This is the primary disagreement between GOLD criterion and the ATS/ERS recommendations that support use of population specific Lower Limit of Normal (LLN) criterion that may vary with age, sex or even ethnicity. Consequently, the stages based upon these ratios are somewhat empirical (Table 80.1). Nonetheless, for practical application, GOLD has made some effort to integrate spirometric classification with clinical picture although the synthesis is somewhat artificial because of imperfect relationship between the two.

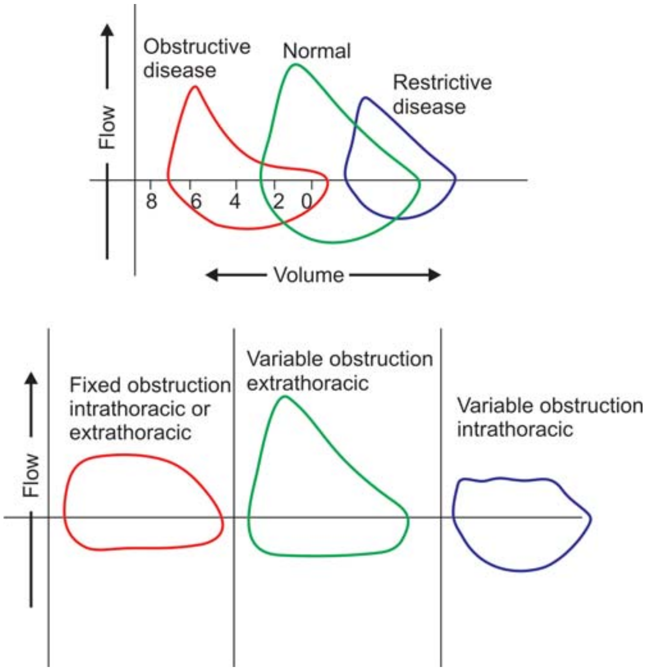

Fig. 80.4: Flow volume loops in some clinical situations as labeled. Extrathoracic obstructions affect inspiration, intrathoracic affect expiration and fixed such as tracheal stenosis affect both.

TABLE 80.1: Summary of GOLD criterion for staging of severity of COPD

Stage I	Mild	FEV1/FVC < 0.7 FEV1 ≥ 80% predicted
Stage II	Moderate	FEV1/FVC < 0.7 50% ≤ FEV1 < 80% predicted
Stage III	Severe	FEV1/FVC < 0.7 30% ≤ FEV1 < 50% predicted
Stage IV	Very Severe	FEV1/FVC < 0.7 FEV1 < 30% predicted or < 50% predicted plus chronic respiratory failure

(Respiratory failure: arterial partial pressure of Oxygen (PaO$_2$) <8 kPA (60 mm Hg) with or without arterial partial pressure of CO$_2$ (PaCO$_2$) greater than 6.7 kPa (50 mm Hg) while breathing at sea level)

Stage I: *Mild COPD* — characterized by mild airflow limitation (FEV1/FVC <0.7; FEV1 >80% predicted). Symptoms of chronic cough and sputum may be present, but not always. The individual is usually unaware that his or her lung function is abnormal because of limitation starting with small airway involvement.

Stage II: *Moderate COPD* — characterized by worsening airflow limitation (FEV1/FVC <0.7; 50% < FVC < 80% predicted), with shortness of breath typically developing on exertion and cough and sputum sometimes also present. This is the stage at which patients typically seek medical attention because of chronic respiratory symptoms or an exacerbation of their disease.

Stage III: *Severe COPD* – characterized by further worsening of airflow limitation (FEV_1/FVC <0.7; 30% < FEV_1 < 50% predicted), greater shortness of breath, reduced exercise capability, fatigue, repeated exacerbations that almost always affect the patients' quality of life.

Stage IV: *Very Severe COPD* – characterized by severe airflow limitation (FEV_1/FVC <0.7; FEV_1 <30% predicted or <50% predicted plus chronic respiratory failure). Respiratory failure might lead to signs of right heart failure such as elevated Jugular Venous Pressure (JVP), pitting edema at ankles and cor pulmonale due to effects on the right heart. Patients may also have Stage IV (Very Severe COPD) even with FEV_1 more than 30 % predicted if any of these complications are present. At this stage, the quality of life is appreciably impaired and exacerbations may be life threatening.

Since degree of airflow limitation correlates only modestly with the symptomatic disability, GOLD emphasizes that the spirometric classification is an educational tool and a pragmatic approach towards the initial management of the patient. It also suggests that the symptomatic impact of the disease should be taken into account because cough and sputum may precede the airflow limitation by years and hence may be important indicators for identifying the individuals at risk for developing COPD. Importantly, in the 2008 update, the previous category labeled as Stage 0, aimed at identifying "at risk individuals" who were defined as "chronic cough and sputum without spirometric abnormality" has been dropped. This is because these individuals do not necessarily progress on to Stage I. Nevertheless, the message that chronic cough and sputum are not normal is unchanged as before. Also, contrary to the earlier hopes of bronchodilator reversibility testing being a predictor of progression in COPD; unlike asthma, this test is now more or less abandoned except for a few indications. No clear relationship has been found between bronchodilator reversibility and disease progression. This was further complicated by increased probability of subjects with low initial FEV_1 being categorized as reversible, even with absolute increase in FEV_1 (200 ml) criterion being included. The test is presently indicated only for atypical COPD patients with history of childhood asthma or nigh-time awakening with cough and wheeze. The protocol for the same can be found in GOLD guidelines.

Limitations

There is a clear scope to improve upon the current spirometry based guidelines because of its limitations at the two ends of the disease spectrum, namely early disease and advanced disease. Small airway disease, which is an early marker of obstructive airway diseases such as COPD and asthma, is hard to detect by spirometry. This has been shown in clinical trials,[21,22] and is understandable in physiological terms because spirometry starts with a full inhalation to total lung capacity and operates over high lung volumes for most of the FEV_1 portion, thereby masking small airway disease. While indices related to the later part of the curve operating at low lung volumes, such as FEF25, are more sensitive to small airway disease, technical variability often precludes reliable use of these parameters. Very recent studies in COPD subjects report that more accurate quantification of small airway disease by Impulse Oscillometry correlates very well with the symptomatic disability and St George's Questionnaire measures.[23] This is discussed further in the next section.

Conventional spirometry also fails to live up to the expectations in severe disease. When a patient with severe COPD makes a maximal expiratory effort, he succeeds only in causing significant thoracic gas compression because the thoracic cage contracts, yet the gas cannot leave because of severely diminished airflow. This gas compression leads to distortion of the volume-flow relationship, inaccuracy of the FV loop and exaggerated estimates of flow limitation. In fact, if such patients were to make a sub-maximal effort, they would generate better airflow. This is a well-recognized problem that has been addressed by the late Dr Joseph Rodarte's group.[24] Another important problem inherent to the current guidelines is that, they paradoxically use failure of therapeutic (bronchodilator) response for the diagnosis of COPD, yet propose to guide the therapy with the same test. However, in absence of other widely available alternatives, this represents a best possible solution focused at identifying declines in lung function and taking corrective measures.

MEASURING SMALL AIRWAY DISEASE: IMPULSE OSCILLOMETRY

As discussed in the above section on spirometry and in the introductory section in physiology, a major limitation of spirometry is that it neither truly measures resistance nor is sensitive to small airway disease which may identify early COPD. Early detection offers an opportunity for early intervention and perhaps delayed progression. Impulse oscillometry, a forced oscillation based technique appears to be particularly promising in this regard[25,26] and is discussed in detail below.

Forced Oscillation Technique

Forced Oscillation Technique (FOT) is advancement in the direction of measuring pulmonary function by allowing measurements of central and peripheral respiratory resistance, without the need for performing any maneuvers. This allows the testing to be performed in subjects incapable of performing the maneuver and excludes the possibility of introducing changes in airway physiology that are attributable to the maneuver itself. As an example, investigators have observed that a forced expiration itself causes bronchoconstriction in individuals who have a tendency to develop bronchospasm. Therefore, the first measurement, which most often is not the best, affects the following measurements being performed in the same test. It has been noted previously that the deep inhalation that precedes the forced expiration, limits the ability to detect modest peripheral airway obstruction.[27]

The principle of the technique has been discussed in the section on physiology. Briefly, it uses superimposing or "forcing" external pressure signals upon the tidal volume breathing of the individual. The flow changes introduced by these small pressure changes are then utilized to calculate the "impedance of the respiratory system," as discussed earlier. The term resistance is replaced with impedance here because the pressure being applied is not constant but consists of mono- or multi-frequency sinusoidal pressure signals. In other words, it is analogous to an Alternating Current (AC) electrical circuit rather than a Direct Current (DC) one. An AC circuit has an "in phase" (real) component of impedance known as resistance and an "out of phase" (imaginary) component of impedance called reactance. Reactance can be further partitioned into the "energy storing and returning" component analogous to capacitance and an inertial component called inertance analogous to inductance in the electrical circuit theory. It is worth mentioning that the clinical use of the technique does not require much technical understanding, although an understanding of both is recommended for research related use.

A pure sinusoidal pressure wave is the basis for the monofrequency forced oscillation technique, whereas multifrequency pressure waves are utilized in multifrequency Pseudo Random Noise FOT. Impulse Oscillometry (IOS) is a further advance that utilizes time-discrete pressure impulses (signals) rather than continuous signals, providing excellent temporal and spatial resolution. These signals are sufficiently different from the spontaneous respiratory patterns of people and do not require any special instructions to the patient in terms of breathing pattern. Impedance is a function of the forcing frequency and must be interpreted in this context. At low frequency (5 Hz), the pressure wave is able to influence flow in the entire lung, including the peripheral airways; while at higher frequencies (e.g. 20 Hz), it primarily influences the upper and central airways. Therefore, resistance at 5 Hz (R5), which is the real part of impedance, denotes the resistance of the total respiratory tree; while R20 corresponds to the upper and central airways. It can be seen that R5-R20 is a measure of peripheral airway resistance. Thus, IOS has a distinct advantage of giving differentiated spectral values of impedance at different frequencies. These parameters are quite well studied and interpreted, although there is a much wider scope to the analysis of these measurements than is presently being employed.

Performance of the Test

The test is performed during normal tidal breathing. This makes it particularly attractive at extremes of age and in those where comprehension or circumstances, e.g. mental illness, post-surgical state, prevent performance of maneuvers. Specifically in IOS, a short reading of about 30 seconds with tidal volume breathing and impulses delivered at 0.02 second interval is recommended. Specific questions may be addressed by changing the impulse rate and the length of recording. The individual sits straight and relaxed while breathing in a relaxed manner. Swallowing movements or glottic closure is best avoided as they can cause artefacts in the reading. To avoid the dissipation of pressure at the cheeks, it is recommended to have hands kept on them, while the nose is closed off by using a nose clip.

	Pred	Act1	%(Act1/Pre)	Pred-Act1
Z at 5 Hz [kPa/(L/s)]	0.32	1.18	363.9	– 0.85
R at 5 Hz [kPa/(L/s)]	0.32	0.91	283.1	– 0.59
R at 20 Hz [kPa/(L/s)]	0.28	0.35	124.0	– 0.07
X at 5 Hz [kPa/(L/s)]	– 0.04	– 0.75	1923.2	071

Fig. 80.5: Representative IOS traces from normal (above) and COPD (below) subjects. Note the frequency dependence of R in COPD such that R5 >R20 as well as an absolute increase in R suggestive of peripheral and generalized airway obstruction respectively. Note the increase in R5 relative to R20 in COPD patient. Also note increase in total impedance at 5 HZ (Z5) during expiration in COPD.

TABLE 80.2: IOS Parameters and typical reference values

IOS Parameters	*Typical Values**
Z5 (Total impedance at 5Hz)	0.33
R5 (Resistance at 5 Hz)	0.31
R20 (Resistance at 20 Hz)	0.30
X5 (Reactance at 5 Hz)	–0.07
Fres (Resonant Frequency)	9.11
AX (Area under the reactance curve)	1.4

*These values are for a normal Indian male, 165 cm tall, 65 kg weight. More than 50% elevation is considered abnormal.

Interpretation

A summary of the measured indices is shown in Table 80.2.

Healthy lungs typically show R and Z values not more than 50% higher than the standard reference values calculated from age, sex, height and weight. Such equations are not yet published for India, but will be released soon. Our initial experience suggests that normal Indian values for these are somewhat higher than for western populations, especially in small-statured women, presumably due to smaller lungs. In health, R is minimally frequency dependent (Fig. 80.5) with R5-R20 being very low. Resonant frequency in adult subjects is typically less than 12 Hz. While a number of diseased patterns are described relating to peripheral airway obstruction, central airway obstruction and extrathroracic obstruction, a full discussion is beyond the scope of this chapter. In COPD, the pattern is typically of small airway obstruction, where R is increased beyond normal and R5 >R20. Almost invariably an increase in Fres and Ax is also seen. A volume dependence of R and Z can be seen such that they increase during expiration. IOS is extremely sensitive to small airway disease and correlates better with the symptomatic disability and St. George's Questionnaire measures than spirometry.[22]

Limitations

Impulse oscillometry is not useful for the diagnosis of restrictive lung disease, since its emphasis is on resistances, not volumes. While Fres is increased in restrictive lung disease, that is a non-specific sign. It should be noted that an IOS system is technically equipped for spirometry since it measures flow, which like spirometers is integrated to measure volumes. Thus, IOS is a highly promising approach in COPD. Continuing education of health practitioners about newer techniques and application of these at a larger scale might be a good initiative in defining COPD in a better way.

OTHER TESTS

Body Plethysmography

Whole body plethysmography, more commonly known as body box because the patient sits inside a closed box, allows determination of airway resistances and Thoracic Gas Volumes (TGV).[28] For any small instantaneous change in thoracic volume of the breathing subject, there is a corresponding opposite change in the box gas volume, which is detected as a box pressure change. Coupled with measurements of airflow at the mouth of the subject, this permits determination of Specific Airway

Resistance (sRaw). While techniques permitting measurements during natural breathing exist, commonly used commercial implementations require the patient to breathe in a fast and shallow pattern, similar to panting. This minimizes the glottic resistance and temperature artefacts, permitting estimation of sRaw from the slope of the trace between changes in box pressure versus airflow at the subject's mouth.

Specific airway resistance is an accurate and sensitive index of airway obstruction, being relatively independent of lung volumes and therefore insensitive to hyperinflation induced airway dilation. Interruption of airflow during panting by a shutter permits estimation of TGV from the trace between mouth pressure and box pressure. This can be readily understood as an application of Boyle's law to a closed (by shutter) thoracic gas compartment for which change in pressures during expansion and contraction is known, i.e. $PV = \text{constant} = (P+dp)(V+dV)$; $V=P(dV/dp)$ where P is atmospheric pressure and V is FRC, dP is pressure change at mouth during shutter occlusion, dV is change in thoracic volume obtained from box pressure signal. Knowledge of true FRC permits calculation of other lung volumes such as TLC, RV, etc. Lung volumes estimated by body plethysmography reflect the total compressible gas during breathing even if communication to airways is reduced or absent. Thus, volume measurements by plethysmography are superior to gas dilution methods in COPD, because of insensitivity to airway occlusion and closure that would otherwise cause systematic underestimates.

Spirometry can also be performed in the body box setup. Body box spirometry is free of compression artifacts mentioned previously and is more reliable than conventional spirometry in patients with severe COPD; however, it is technically more demanding. In addition to the regular calibration of airflow similar to spirometry, the equipment also needs to be calibrated daily for ambient conditions (room temperature, atmospheric pressure and humidity), box calibration (leak test result should typically be between 4 and 7s) and volume calibration. Regular calibration of volume and assessment of the dynamic responsiveness of the system to oscillating signals is particularly recommended. This is usually accomplished by alternately injecting and removing known volumes into the sealed body box by a piston or pump. Very importantly, the calibration factor requires adjustment for the air displaced when a subject is seated inside the box. This is a part of the standard analysis and the users only have to input correct values for the subject's weight. Importantly, patients must be adequately instructed for performance of suitable panting such that the traces obtained are reproducible and near-linear in the central regions of the trace. When used appropriately, the body box is a very sensitive pulmonary function test that can accurately measure the various components of COPD and distinguish between predominant emphysema and predominant bronchitis.

Peak Expiratory Flow Rate (PEFR)

Contrary to asthma, where peak expiratory flow has a distinct role in the management, it has a limited role in COPD management because the peak flow might be relatively well preserved, despite the FEV_1/FVC ratio being low. Therefore, there is a weak correlation between the two, limiting its use in management of COPD.[29]

Helium Diffusion

Equilibration of known quantity of an inert gas that is neither consumed nor absorbed with the lungs followed by measurement of the concentration postequilibration permits determination of the unknown equilibration volume, i.e. lung volume. While this is a commonly used test in many conditions, it tends to systematically underestimate lung volume in COPD patients because equilibration can be slow and incomplete.[30]

Transfer Factor (TLCO and KCO)

This is a quantitative test for the quality of oxygen transfer across the lungs. It is based on measurement of the relative transfers of Carbon Monoxide (CO) and helium, when inhaled as a mixture. Helium is an inert gas and the concentration in the expired air is lesser than inspired air because of dilution with the resident gas in the lungs. On the other hand, CO is a surrogate for Oxygen, since it additionally crosses the alveolar membrane and binds tightly to hemoglobin. Knowing the inhaled concentrations of these two gases, one can calculate the transfer factor expressed either as CO transfer factor (TLCO) or transfer factor per unit lung volume accessed (diffusion coefficient) to correct for nontransfer across the areas of lung which could not be accessed (e.g. pleural effusion). This is also known as Carbon Monoxide Transfer Coefficient (KCO). KCO tends to be high in airway disease, such as asthma, except when severe. Emphysema causes a fall in KCO because of loss in the area available for gas transfer by creating large airspaces and destruction of alveolar-capillary membrane. Hence, in an individual known to have COPD, KCO is a marker for the extent of emphysematous change in the lung. The utility of this test is limited by its nondiscriminatory power as KCO also decreases in conditions where restrictive or vascular changes are present in the lung.[29]

Fraction Exhaled Nitric Oxide (FENO)

Although there is limited experience with this test in COPD patients, this might be useful in distinguishing cases where asthma seems to be a possible component of airflow limitation. This is because asthma, particularly of the "Atopic" variety is characterized by higher levels of nitric oxide exhaled in the breath. This is correlated with the amount of eosinophilic inflammation in the airways and excellent reviews are available explaining the molecular mechanisms and the sites for generation of NO in airways.[31] The reader is encouraged to refer to these for further application.

THE FUTURE

Anticipated future trends in pulmonary function testing are described as follows: [32]

- Standardization with more physicians embracing the benefits of following common international guidelines; this seems inevitable
- Focus on early detection: It is increasingly recognized that onset of COPD predates onset of diagnostic changes in spirometry by many years. We hope that new guidelines will address this lacuna and move away from sole emphasis on airflow limitation.
- Convergence and portability of technology: Miniaturization of technology has already significantly reduced the size of PFT equipment. This coupled with uniform standards, has permitted new-generation devices with high user friendliness to penetrate the nonspecialist market.
- Innovative web-based applications, such as tele-PFT, e-learning and Internet-based distance education, are also likely to result in a paradigm shift in coming years.

Systemic Manifestations and Comorbidities

SK Jindal, PS Shankar

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD), a syndrome of progressive airflow limitation caused by an abnormal inflammatory reaction of the airways and lung parenchyma, is now considered a systemic disease with widespread extrapulmonary manifestation.[1-6] The comorbid conditions, in association with pulmonary manifestations, pose additional problems of management. There is a resultant increase in the overall morbidity, mortality, health care burden and costs. In view of the recognition of the multisystem involvement and manifestations, the disease in future may be well classified and discussed amongst systemic than the pulmonary diseases.

PATHOGENESIS

The mechanisms of systemic manifestations are not completely understood. The pathogenetic process initiated in COPD is likely to have a variety of effects on target tissues. The pathologic changes in the lungs, such as peribronchial fibrosis, airway narrowing, destruction of alveolar walls and loss of elastic recoil lead to airflow limitation. An imbalance between oxidants and antioxidants plays an important role in the pathogenesis of COPD. Reactive oxygen species generated by neutrophils are removed by blood antioxidants and antioxidant enzymes. Thus, the ability to prevent the injurious effects of oxidative stress depends on the antioxidant capacity of the blood and the tissues. There is a marked oxidant-antioxidant imbalance in smokers and during acute exacerbations of COPD.[7] The increased oxidative burden is also likely to cause changes in fibrinolysis contributing to atherosclerosis.

The following mechanisms have been postulated to explain the pathogenesis of COPD:

Mediators and Cytokine Spillover from Lungs

There is an increase in the circulating levels of a variety of cytokine mediators such as Interleukin (IL)-1 beta, IL-6 and Tumor Necrosis Factor (TNF)-alpha and Interferon (IF)-gamma and leptin in patients with COPD.[8-18] Migration and activation of inflammatory cells is regulated by cytokines and chemokines, secreted by epithelial cells, endothelial cells, smooth muscle cells, fibroblasts and inflammatory cells. The systemic effects, however, are not directly attributed to the changes in the lungs. Possibly they are caused by low-grade systemic inflammation due to the presence of numerous inflammatory mediators and cytokines released from the lungs into the systemic circulation, i.e. lung to plasma spill-over.[2,11-13]

A large number of cytokines, chemoattractants and other mediators have been identified. Neutrophil granulocytes are the key players and the most important chemoattractants seem to be IL-8 and Leukotriene B4 (LTB4).[14]

Attempts have been made to study their role through analyses of exhaled air condensates. Inflammatory cytokines have been isolated from sputum exhaled breath condensate and Bronchoalveolar Lavage (BAL) fluid from COPD patients.[15] However, unlike in asthma, the findings in COPD have not been very helpful. Inflammatory markers in the blood [e.g. IL-6, C-Reactive Proteins (CRPs) and fibrinogen] have been also studied.[12]

Systemic inflammatory markers in COPD were assessed in the large Bergen COPD Cohort Study on 409 patients and 231 healthy subjects aged 40–75 years.[12] Plasma levels of CRP, Soluble Tumor Necrosis Factor (sTNFR)-1, osteoprotegerin neutrophil activating peptide-2, CXCL16 and chemoattractant protein-4 were determined by ELISA tests. COPD patients had significantly lower levels of osteoprotegerin and higher levels of CRP. Soluble tumor necrosis factor-1 was significantly associated with important comorbidities such as hypertension and depression. It was thus concluded that the presence of these circulating inflammatory mediators was an important phenotypic feature of COPD.

Peripheral Blood Inflammatory and Other Cells

The evidence from other cross-sectional studies show no clear association between lung and systemic inflammation, which suggest that the systemic inflammatory response is not caused by the “spill-over” or overflow of inflammatory mediators from the pulmonary circulation, but by the systemic peripheral, inflammatory cells such as the neutrophils and lymphocytes.[18,19] There are several other cells including the macrophages and the mononuclear cells, which are attracted by mediators such as CCL2 and CCL3. Involvement of T-lymphocytes especially the cytotoxic $CD8^+$ cells has been also postulated.

The presence of hypoxia in severe COPD may also be responsible for an increased production of cytokines which activate TNF-alpha and soluble TNF-R.[20] It is also possible that the inflammatory mediators are produced by the muscle cells or other extrapulmonary cells located in the endothelium and fatty tissue.[21]

While it is likely that different systemic manifestations are explained by different mechanisms, the concept of inflammation as responsible for multisystem involvement has been clearly established. The understanding of these pathogenetic mechanism is expected to change the clinical practice and pharmacotherapy of COPD.[22-26]

SYSTEMIC MANIFESTATIONS

There are a large number of systemic features and comorbidities seen in COPD (Table 81.1). Interestingly some of the general clinical features, such as weakness, weight loss, anxiety, depression and others earlier considered as “vague” or nonspecific in nature, are now identified as more definitive and significant manifestations of nonpulmonary system involvement and they are described as follows:

TABLE 81.1: Important systemic manifestations of COPD

1. General:	Wasting and weight loss, Nutritional anomalies, anemia
2. Musculoskeletal:	Skeletal muscle dysfunction Osteoporosis Reduction in exercise tolerance and performance
3. Cardiovascular:	Pulmonary vascular disease/ Chronic cor pulmonale, ischemic heart disease— acute cardiac events Cardiac failure Stroke
4. Endocrinal:	Diabetes Metabolic syndrome Dysfunction of pituitary, thyroid, gonads and adrenals
5. Neuropsychiatric:	Depression Disordered sleep Anxiety Cognitive function decline

Wasting and Weight Loss

Muscle wasting and weight loss are common manifestations of COPD. The Body Cell Mass (BCM) is the actively metabolizing and contracting tissue. The alterations in BCM, recognized clinically by weight loss, essentially pertain to loss in Fat-Free Mass (FFM) in COPD. Loss of FFM adversely affects muscle aerobic capacity and exercise capacity.[27,28] Weight loss appears to arise from an increased basal metabolic rate occurring due to an increased work of breathing. Inhaled salbutamol, altered amino acid composition and tissue hypoxia may result in an increased metabolic rate.[29-31]

Acidosis, infection, alteration in body composition and changes in intermediate metabolism or inadequate caloric intake, especially during acute exacerbations of the disease, are associated with an increased breakdown of cell proteins, especially in muscles. An important relationship is likely with acute exacerbations.[32] There is preferential loss of skeletal muscles, especially in the lower extremities in patients with COPD. The muscle wasting is increasingly noticed in quadriceps muscles. Physical inactivity leads to quadriceps muscle weakness in patients with advanced COPD. Quadriceps muscle weakness is related to low circulating levels of testosterone in men with COPD.[33] Histologic study of biopsy specimens obtained from the quadriceps of patients with COPD has shown a loss of aerobic type I fibers and a reduction in oxidative enzymes.[34,35] It has been hypothesized that inflammatory cytokines may contribute to muscle wasting through the inhibition of myogenic differentiation.[36]

The mechanisms underlying weight loss and muscle wasting are incompletely understood, but likely to involve an imbalance in an ongoing process of protein degradation and replacement. It may include alteration in the relative levels or activities of endocrine hormones such as insulin, growth hormone, testosterone and glucocorticosteroids.[37]

Skeletal Muscle Dysfunction

The patients with COPD exhibit skeletal muscle dysfunction characterized by muscles atrophy and diminished strength.[38] It also results in marked reduction in exercise capacity.[39] Among the muscles, diaphragm is put into constant work and it has to work against an increased load. Other skeletal muscles are utilized less due to inactivity.[40]

Skeletal muscle dysfunction is likely to occur from sedentary lifestyle, tissue hypoxia and systemic inflammation.[39] Systemic inflammation, causing muscle dysfunction, is the result of the effects of cytokines such as TNF-alpha, IL-6 and IL-8, and oxidative and nitroactive stress.[41] They are likely to cause protein inactivation and degradation leading to dysfunction, atrophy and apoptosis.[42] It must be noted that an increased inflammation in the lung does not correlate with increased levels of circulating inflammatory markers.

The circulating neutrophils appear to be activated in patients with COPD and they show enhanced chemotaxis and extracellular proteolysis.[43] They produce greater amount of reactive oxygen species.[44] Besides low-grade systemic inflammation, nutritional depletion, corticosteroid medication, chronic inactivity, age, hypoxemia, smoking, oxidative and nitrosamine stresses, protein degradation and changes in vascular density are some other factors contributing to muscle dysfunction in COPD.[45]

Weight loss and skeletal muscle dysfunction cause limitation in the activities and the exercise capacity of the patient with COPD and indirectly on the quality of life. There is worsening of exercise tolerance and performance, increased health care utilization and increased mortality.[46,47] Muscle weakness is recognized to contribute independently to poor health status. Some of these manifestations, i.e. body mass index, degree of air flow obstruction, dyspnea and exercise capacity (the BODE index), have been used as measures of disease severity and mortality risk in COPD.[48-50]

Cardiovascular Problems

Cardiovascular system has a complex interaction with the respiratory system.[51] Pulmonary vascular abnormalities are common in the presence of a chronic lung disease such as the COPD. Pulmonary hypertension, right ventricular dysfunction and chronic cor pulmonale have been recognized since long.[52-54] It is now known that structural changes in pulmonary arteries can occur early in COPD before the onset of hypoxemia.[55] Systemic inflammation, atherosclerotic coronary heart disease and cardiovascular deaths are known as important complications of COPD.

Cardiac failure was seen in 10% to 46% of patients of COPD, while 40% of patients with cardiac failure showed some evidence of COPD, about half of whom were not earlier recognized.[56] There is enough data from epidemiological and other studies to show that atherosclerosis and coronary artery disease are associated with decline in Forced Expiratory Volume in One Second (FEV_1). The risk for cardiovascular death was 75% greater for patients who had a lower FEV_1.[57] Cardiovascular death was also shown to increase by 28% and hospitalization for cardiovascular causes by 42% for every 10% decline in FEV_1.[58] Arrhythmias in COPD are common, but rarely fatal. The right ventricular arrhythmias are more often seen in the presence of chronic cor pulmonale.

The occurrence of both COPD and coronary artery disease is possibly due to the shared risk factors, such as tobacco smoking, as well as to the similar pathogenic mechanisms, i.e. systemic inflammation.[59]

Endocrinal Disorders

A number of endocrine functional disorders have been described in COPD.[60] Derangements of pituitary and thyroid function, gonads and adrenals have been seen in some studies. Diabetes along with other manifestations of metabolic syndrome has been described especially in the presence of cardiovascular disease.[2,56,59,61]

Several mechanisms have been proposed to cause endocrine dysfunction — hypoxemia, hypercapnia, systemic inflammation and glucocorticoid administration for airway obstruction. The presence of endocrine imbalance increases the overall morbidity and cardiovascular risks. The decreased protein anabolism and increased catabolism affect the body mass and also accounts for muscle dysfunction. Altered renin-angiotensin-aldosterone function affects the blood flow, fluid balance and the renal function. Other systemic effects of endocrinal disorders include the disturbances of control in breathing, worsening of respiratory mechanics and impairment of cardiac function.[60]

Neuropsychiatric Derangements

Depression and anxiety are more common in COPD than in healthy age-matched controls.[62,63] Disordered sleep is commonly ascribed to hypoxemia, hypercapnia and diminished ventilatory responses.[64,65] It is further aggravated by the concomitant presence of nocturnal respiratory symptoms, anxiety and depression. Obstructive sleep apnea is present in about 10 to 15% patients of COPD ("overlap syndrome").[65] The other sleep disturbances seen in more than half of the COPD patients include the diminished arousal responses, longer latency in falling asleep, more frequent awakenings or generalized insomnia.[66] The severity of sleep disturbances increase with the severity of disease.

Impairment of intellectual function is also common.[67] The cognitive decline, along with other neuropsychiatric problems, is attributed to the presence of hypoxemia and has shown to improve with long-term oxygen therapy in some small studies.[68] More work requires to be done on the subject.

Osteoporosis

Osteopenia and osteoporosis were reported in 68% of patients with COPD.[69] Osteoporosis may lead to generalised bony pains, compression fracture of the spine and compromised lung function due to kyphosis and thoracic vertebral compression. Corticosteroid therapy, including inhaled steroids, is generally considered responsible for osteoporosis; although in one study, compression fractures were reported in 49% of patients who had COPD and had never received steroids.[70]

THERAPEUTIC CONSIDERATIONS

The recognition of systemic features has made the greatest impact on clinical course, complications and therapy of COPD. The variable host response and subsequent clinical phenotyping has made it possible to develop a targeted treatment with the help of a multisystem approach.[71] Some of the treatment failures are possibly due to the phenotype heterogeneity of COPD and its different systemic manifestations. The future treatments with statins, angiotensin-converting enzyme inhibitors and anti-inflammatory drugs, targeting the comorbid conditions, may help to change the natural history of COPD and improve the mortality.[24-26] There are several novel anti-inflammatory drugs such as the phosphodiesterase-4 inhibitor and other inhibitors of nuclear factor—κB and p38 mitogen-activated protein which may prove beneficial. Antioxidants may also help to control comorbidities.

Lastly, it is shown that the elderly patients, who are at an increased risk of almost all the comorbidities of COPD discussed earlier, may benefit from the treatment of concomitant comorbidities. Further, development of anti-aging molecules, such as sirtuin agonists, can be helpful and may also reduce the risk of lung cancer.[25] It should however not be overlooked that aging alone is not an exclusion criterion for pulmonary rehabilitation and other treatment of COPD.[72] Assessment and appropriate treatments of COPD and the comorbid conditions has been shown to provide similar benefits of management.

Role of Infections in Chronic Obstructive Pulmonary Disease

Suruchi Mandrekar, Sundeep Salvi

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is the fourth leading cause of mortality worldwide, anticipated to become the third by the year 2020.[1,2] The role of infections in COPD is poorly understood and highly underestimated. Infections not only play a pivotal role in initiation and progression of COPD, but also affect the clinical course of COPD. Historically, bacteria have been considered as the main infectious cause of COPD exacerbations.[3] However, a growing body of evidence, has implicated viral respiratory infections in the exacerbations of COPD.[4,5] Recent studies have shown the role of both viruses and bacteria in the initiation and progression of COPD.

DO BACTERIA CAUSE/INITIATE COPD?

Bacterial Airway Colonization: Initiation of COPD Inflammation

In a normal healthy subject, the respiratory tract is almost always sterile. In a stable chronic bronchitis patient, the sputum produced is usually mucoid and scant. Even during these quiescent periods, cultures of sputum have yielded presence of potentially pathogenic bacteria in around 25 to 50% of cases.[6] Organisms including nontypeable *Haemophilus influenzae, Moraxella catarrhalis* and *Streptococcus pneumoniae* have been found to be the predominant bacteria in early studies. Once these bacteria colonize the lower airway, they can directly cause airway inflammation and impair mucociliary clearance, thereby perpetuating a vicious circle of impairing local defenses.[7]

TABLE 82.1: Role of bacterial infections in COPD

- Chronic childhood lower respiratory tract infection impairs lung growth
- Chronic colonization induces a chronic inflammatory response
- Chronic infection alters the host response to cigarette smoke
- Acute exacerbations of chronic bronchitis
- Bacterial antigen induced hypersensitivity and bronchial hyperreactivity

Several putative roles of bacterial infection in the etiology, pathogenesis and the clinical course of COPD have been identified (Table 82.1).[6,7]

Childhood Infection and Adult Lung Function

Several studies have shown a lower Forced Expiratory Volume in One Second (FEV_1) and often a lower Forced Vital Capacity (FVC) among adults who experience recurrent lower respiratory tract infection during childhood.[7,8] This association has been observed even after controlling for confounding factors such as tobacco smoke and other exposures. The defect in lung function is consistent with “smaller lungs,” suggesting impaired lung growth. The extent of decrease in FEV_1 is unlikely to cause symptomatic pulmonary disease on its own, but make the individual further susceptible to the effects of additional injurious agents such as tobacco smoke and other environmental insults. The impact of childhood bacterial lower respiratory tract infection on the prevalence of COPD is likely to be greater in developing countries where there is a high incidence and inadequate treatment of these infections.[8]

Bacterial Colonization Central to Progression of COPD: Vicious Circle Hypothesis

In the absence of any underlying lung disease, the tracheobronchial tree is sterile. However, in patients with COPD, tobacco smoke and other environmental insults cause damage to the airway epithelium and impair mucociliary clearance of the tracheobronchial tree. Chronic colonization with potential respiratory pathogens, predominantly nontypeable *H. influenzae* (NTHI), *S. pneumoniae* and *M. (Branhamella) catarrhalis*.[9,10] Once the bacterial pathogens have gained a foothold in the lower respiratory tract due to impaired mucociliary clearance, they persist in the airway mucosa as bacterial colonizers and further impair the mucociliary clearance by releasing a whole host of bacterial products which cause airway epithelial injury (Fig. 82.1).[11]

Bacterial Infection and Mucociliary Clearance in COPD: A Role in Initiation of COPD Inflammation

The tracheobronchial ciliary escalator is of paramount importance in maintaining the sterility of the lower respiratory tract by transporting bacteria trapped in mucus towards the pharynx.[12]

Disruption of this ciliary activity is therefore likely to play an important role in the establishment of a chronic colonization in the tracheobronchial tree. Rapid inhibition of ciliary beat frequency has been seen with *Nontypeable Haemophilus influenzae* (NTHi) and *Pseudomonas aeruginosa,* but not with *Staphylococcus aureus.*[13] On direct microscopic examination, ciliary dyskinesia and ciliostasis is also seen. Human neutrophil elastase, released by activated neutrophils, further inhibits ciliary activity and damages respiratory epithelium.[13,14] Bacterial products released in the airways act as a potent stimulus for neutrophil migration into the airways, elastases released from these chemotactic neutrophils act synergistically with bacterial products and cause airway epithelial injury and further inhibition of tracheobronchial ciliary function.

Bacterial Infection and Airway Epithelial Injury

An important component of the vicious circle hypothesis is the potentially damaging effects of bacteria and bacterial products on airway epithelial lining cells. In an *in vitro* tissue culture model of nasal turbinate epithelium, Read et al.[15] have demonstrated that NTHI is capable of causing airway epithelial injury. They studied infected airway epithelia after 30 minutes, 14 hours and 24 hours of incubation with a NTHI strain. At 30 minutes, the airway epithelium and cilia were intact and the bacteria were found associated with the overlying mucous layer. At 14 hours, patchy injury developed to the airway epithelium, with bacterial cells now associating with these damaged epithelial cells but not with intact epithelium. At 24 hours, detached epithelial cells with adherent bacteria were seen. Such epithelial injury in the large airways would contribute to bacterial persistence and in the small airways contribute to the respiratory bronchiolitis that causes progressive airway obstruction. This study demonstrated that bacteria that colonize and infect the lower respiratory tract in COPD are capable of fostering in the tracheobronchial tree—an environment in which they can persist, supporting the central tenet of the vicious circle hypothesis (Fig. 82.1).

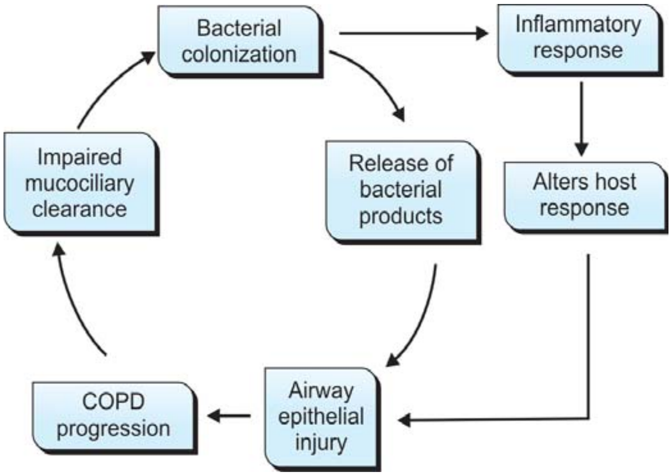

Fig. 82.1: Bacterial colonization contributing to COPD progression

Bacterial Infection and Airway Inflammation

The presence of bacteria in the lower airways in patients with stable COPD has been labeled as *colonization*. Recently, more attention is being directed towards the possible effects of bacterial products and their chronic inflammatory response on the elastase-antielastase balance in the lung. This abnormal bacterial colonization of the tracheobronchial tree is not only confined to the large airways but has been shown to extend to the peripheral airways also by bronchoscopic protected specimen brushings culture.[16] Interestingly, it was observed that even during colonization, bacteria in these airways were likely to be in a constant state of turnover, releasing extracellular products, undergoing lyses and releasing a variety of proteins, Lipooligosaccharides (LOS) and peptidoglycans. These LOS are a potent source of inflammatory stimulus, which have been shown to be associated with the development of emphysema in animal models.[17] In the large airways, such inflammation would contribute to excess mucus production while in the smaller airways, it would contribute to the development of respiratory bronchiolitis and progressive airway obstruction.

The Role of infections: COPD Exacerbations

Periods of acute worsening of COPD, termed "exacerbations," greatly affect the quality of life and health of patients and place a greater burden on the health services.[18] Chronic obstructive pulmonary disease is characterized by exacerbations, which are caused mainly by infections of the tracheobronchial tree or by inhalation of toxic gases. During an exacerbation, the underlying airway inflammation is augmented and there is a sustained worsening of patient's condition from the stable state. Chronic obstructive pulmonary disease exacerbations are a major cause of hospital admissions, frequent exacerbations and are associated with increased mortality and impaired health-related quality of life.[19] Previous studies have reported that patients who experience frequent exacerbations present with an accelerated rate of lung function decline.[20,21] Increased frequency of exacerbations also increases the disease severity. Management of exacerbations should aim at a prompt diagnosis, effective and optimum treatment that would reduce exacerbation frequency.

Historically, bacteria have been considered to be the main infectious cause of exacerbations. A growing body of evidence, however, implicates viral respiratory tract infections as an important risk factor associated with COPD exacerbations.[3,5] Though bacteria plays a very important role in colonization and progression of COPD, acute viral infections are usually the first and primary infectious agents during an acute infective exacerbation.

Pathogenesis of Viral Exacerbations

Despite the epidemiologic evidence linking respiratory virus infection to exacerbations of COPD, the exact cellular and molecular mechanisms by which viruses cause exacerbations remain largely undetermined.[3] Several studies have looked into the key issues that drive virus-induced exacerbations of airway diseases.[22] There is now an increasing body of evidence from experimental rhinovirus infections that respiratory viruses that typically cause. Upper Respiratory Infections (URIs) can, infact, infect the lower airways.[22-24] Recent research suggests that many respiratory viruses, including the major group of rhinovirus, attach to airway epithelial cells through Intercellular Adhesion Molecule-1 (ICAM-1). It has been shown that the expression of ICAM-1 is increased on the epithelial cells of bronchi in patients with COPD. Moreover, induction of ICAM-1 expression has been shown to promote the recruitment and activation of inflammatory cells. Viral infection of epithelial cells lead to the destruction of epithelial lining of the airways, the extent of epithelial destruction varies according to virus type. For example, influenza virus typically causes extensive airway epithelial necrosis, whereas infection with rhinovirus results only in patchy damage.

Viral infection of epithelial cells also initiates and regulates the release of proinflammatory cytokines and chemokines such as Tumor Necrosis Factor-Alpha (TNF-á), Interleukin-8 (IL-8), Epithelial-Derived Neutrophil Attractant (ENA-78), Leukotriene B4 (LTB4), CCL5 (RANTES) and endothelin-1.[25-27] The released IL-8, ENA-78 and LTB4 attract neutrophils, which stimulate mucus production and result in increased production of purulent sputum,[27] whereas CCL5 (RANTES) attracts eosinophils, lymphocytes, macrophages and activated T cells, resulting in apoptosis of virus-infected cells.[28] This results in airway inflammation, airway remodeling, tissue destruction and loss of lung function. Endothelin-1 causes bronchoconstriction and vasoconstriction, resulting in airflow obstruction and impaired gas exchange. Interleukin-6 which is also released from epithelial cells during exacerbations induces systemic inflammation which results in cachexia, muscle wasting, depression and vascular events that can characterize severe, complicated exacerbations of COPD.[29,30]

Viral infections, however, often coexist with bacterial pathogens in patients with COPD during exacerbations. Therefore, for severe exacerbations marked by increased dyspnea, increased sputum production and increased purulence, the consideration of the possible role of bacteria and the use of antibacterial agents is indicated.

Management of Viral Exacerbations

In specific circumstances, antiviral agents may be useful for the treatment of COPD exacerbations. The use of oseltamivir, an antiviral drug, in COPD exacerbations appears appropriate only during the presence of an influenza epidemic. The novel capsid-binding inhibitor, pleconaril and the 3C protease inhibitor, rupintrivir, modestly reduce symptoms during human rhinovirus-induced colds. The efficacy of these compounds in patients with virus-induced COPD exacerbations, however, has not yet been fully examined. Anti-inflammatory therapy may have a therapeutic role in

COPD exacerbations[25] and several potential anti-inflammatory treatments are now in clinical development.[31] Future therapies could range from selective inhibitors of key virus-induced signaling pathways in epithelial cells to the antagonists of specific chemokines that may play a key role in pathogenesis.

Intercellular Adhesion Molecule-1 has been specifically described as a potential target to block as a means of preventing rhinovirus infection.[31] Another drug that requires mention is Nitric Oxide (NO). Nitric oxide exerts direct antiviral activity against several viruses associated with exacerbations, also inhibits virus-induced generation of several cytokines from epithelial cells.[32] Traditional methods of preventing the transmission and acquisition of respiratory viruses should be advocated to treat virus-induced exacerbations. Immunization with standard influenza virus vaccine is associated with reduced hospitalization rates, fewer outpatient visits, less severe illness, lower mortality related to pneumonia and influenza in older persons[33-35] and a reduced risk of influenza-related illness in persons with COPD.[36]

Acute Bacterial Exacerbations

Bacteria have been isolated from the sputum in approximately 60% of Acute Bacterial Exacerbation of Chronic Bronchitis (ABECB) cases. The most common isolated organisms include *H. influenzae, Haemophilus parainfluenzae, S. pneumoniae* and *M. catarrhalis.*[6,19-21] The contributions of these four organisms can depend on the severity of underlying airway disease. A number of studies have found more virulent organisms in the airways of severe chronic bronchitis patients with acute exacerbations including *S. aureus, Pseudomonas* species and members of the *Enterobacteriaceae* family.

Bacterial exacerbation is the acquisition of new strains of bacterial pathogens from the environment that are able to establish an infection in the tracheobronchial tree because of the compromised innate lung defenses. These pathogens interact with airway cells, elicit an inflammatory response which underlies the pathophysiology and symptoms characteristic of an exacerbation. An immune response that can be mucosal, systemic or both, develops to the infecting bacterial strain. This immune response contains the infectious process, could eradicate the infecting pathogen and prevent reinfection with the same strain.[37] However, because of the antigenic diversity among bacterial strains, the immunity tends to be strain-specific rather than widely protective.

Other mechanisms contributing to acute bacterial exacerbations include an increase in bacterial load and an interaction with other etiologies such as viruses, which also could contribute to bacterial exacerbations. In general, during ABECB, many of the same bacteria that are found in the airways during clinically stable periods are present, but at higher colony counts.[20] The higher counts lead to an airway bacterial load which crosses the clinical threshold to present with an exacerbation. The role of atypical pathogens such as the *Mycoplasma* and the *Chlamydia* species seems to follow three separate mechanisms in ABECB:

1. Infection with *Chlamydia pneumoniae* infection at an early age can make airways more susceptible to the effects of irritants, such as cigarette smoke, and can increase the risk of chronic bronchitis later in life.
2. Both these species can cause ABECB themselves.
3. Atypical organisms and viruses can cause a primary infection that can lead to severe lower airway inflammation, enabling a secondary increase in bacterial proliferation that can lead to an exacerbation.[5,6,20]

The exact role of bacterial infections in causing COPD exacerbations is however not completely understood because of the following commonly encountered reasons:

- Bacteria are known to colonize the lower airways in COPD patients, even in the absence of symptoms of an exacerbation
- Patients with COPD are highly heterogeneous. As a result, bacteria may vary from patient to patient, likely to play different roles in different individuals
- The information obtained from the cultures of expectorated sputum samples is limited since the samples do not reliably reflect conditions in the lower airways
- Even if bacteria play a role in exacerbations, they probably account for only half of all the infectious episodes in COPD patients
- The three bacteria most strongly implicated in causing exacerbations (nontypeable *H. influenzae, M. catarrhalis* and *S. pneumoniae*) are exclusively human pathogens, limiting the use of animals models to illustrate the role of these bacteria during an exacerbation.

Understanding the Pathogenesis of Acute Exacerbations of COPD (AECOPD)

The pathologic lesions of chronic bronchitis (AECB) involve morphologic changes in both the large and small airways. In patients with chronic bronchitis, these airways contain a marked presence of inflammatory cells with a predominance of monocytes, lymphocytes and CD8+ cells and neutrophils in the airway lumen. In the large airways, inflammation leads to metaplasia of both the columnar and goblet cells that line the epithelium. In addition, there is an increase in the size of the mucus-secreting glands in smooth muscle, connective tissue in the bronchial wall and degeneration of the airway cartilage.[6,37]

There is emerging evidence that ABECBs are associated with increased airway inflammation. There appears to be a clear association between the degree of inflammation and the severity and frequency of the exacerbations. Bronchoalveolar lavage specimens, taken during ABECB, show increase in the absolute number and percentage of neutrophils. Levels of IL-8, LTB4 and Myeloperoxidase (MPO), all have been found to be increased during AECB.

Diagnosis and Management of Acute Bacterial Exacerbation

The clinical diagnosis of ABECB traditionally uses some combination of the original three Anthonisen criteria: Increased cough, dyspnea or increased sputum purulence from baseline. There are no characteristic laboratory and radiographic tests that can confirm the diagnosis of ABECB. Some clinicians have proposed major and minor criteria; the major criteria consist of the original Anthonisen criteria and the minor criteria consist of wheezing, sore throat, cough and symptoms of the common cold, including nasal congestion or discharge. They define an ABECB as the presence of at least two major symptoms or one major symptom and one minor symptom for at least two consecutive days.[18,30]

There are no characteristic physical findings. Some have suggested that severe exacerbations may be associated with body temperatures greater than 38.5°C, although this is highly controversial. Chest radiographs are not helpful in making the diagnosis, but they can indicate pneumonia or other diagnoses, such as congestive heart failure. The exception to this is a patient presenting to the emergency department or being hospitalized where routing chest X-rays may reveal abnormalities that lead to changes in management (16 to 21% of cases). Sputum Gram stain and culture have a limited role in diagnosing ABECB due to the frequent colonization of airways in chronic bronchitis patients. Sputum analysis should be reserved for patients with frequent exacerbations or in patients with purulent sputum in whom there is a suspicion of more virulent or resistant bacteria. Spirometry during an acute exacerbation has little value, but it is important to know the pre-exacerbation state FEV_1 as a predictor of an adverse outcome of ABECB.

Treatment of Bacterial Exacerbations

The treatment of a bacterial exacerbation should be directed towards three major goals:

- Relief of symptoms
- Prevention of transient loss of pulmonary function (can lead to hospitalization)
- Reassessment of the disease in an attempt to reduce the risk of any further exacerbations

Pharmacologic therapy should be aimed at decreasing the work of breathing, decreasing airway inflammation, lowering the bacterial burden of the lower airways and treating hypoxia.

The role of antimicrobial therapy in the treatment of ABECB remains controversial despite numerous therapeutic trials of antibiotics for more than 50 years. Most comparative trials have found equivalence in the use of antimicrobials. Differences in study end points, differences in patients' groups studied[6,18-21,30] and variations in antibiotics, all have made the comparison of these studies difficult. Not all antibiotics, used to treat ABECB, have the same spectrum of activity or pharmacokinetic properties; therefore, numerous factors should be considered when selecting an antimicrobial agent for treating an acute bacterial exacerbation of COPD.

The chosen antibiotic should have both *in vitro* and *in vivo* activities against the most commonly associated pathogens, including *H. influenzae, S. pneumoniae* and *M. catarrhalis*. In certain subgroups of patients with a more severe obstructive disease, coverage might need to be extended to include other pathogens such as *S. aureus, Pseudomonas aeruginosa* and *Enterobacteriaceae* species, and atypical pathogens. While treating an exacerbation, special attention should be paid to local and regional resistance profiles of the major bacterial pathogens.

Antimicrobial therapy is appropriate for patients with an ABECB if they fall into the Anthonisen type I or type II categories but is not warranted in patients with a type III exacerbation. High-risk patients, including patients who have significant pulmonary impairment (FEV_1 <50% or lower than predicted), who have four or more exacerbations per year, or who use supplemental oxygen or chronic oral corticosteroids, should be treated with antibiotics during ABECB. Due to emerging antimicrobial resistance, second-generation macrolides and some second- and third-generation cephalosporins may be used rather than the traditional first-line agents [aminopenicillins, doxycycline, trimethoprim-sulfamethoxazole (TMP-SMX)]. A failure rate of 13 to 25% can be expected with a traditional first-line antibiotic. Patients, who have structural lung disease, chronically use corticosteroids and who frequently use antimicrobials are at higher risk for *P. aeruginosa* infection, and should be treated with antipseudomonal agents such as the fluoroquinolones. Patients who have been treated in the past three months for ABECB and who present with a relapse or recurrence of ABECB, should be treated with a different class of antibiotics based on culture sensitivity.

The Role of Latent Viral Infections in COPD

Acute viral respiratory tract infections are well known to precipitate acute exacerbations, but their role in the pathogenesis and the chronicity of the disease is poorly defined. Very interesting is the role of double-stranded deoxyribonucleic acid viruses which have the ability to persist in airway epithelial cells long after the acute infection has cleared. During these latent infections, viral genes are expressed at the protein level without replication of a complete virus. The host responds to a viral insult through two immune components; an innate immunity and an adaptive immune response. This innate component is fully functional before the virus enters the host airway epithelium.[37,38] The adaptive component develops in response to the presence of the virus inside the airway epithelium.[38,39] The innate response is triggered before the adaptive immune response and generates cytokines that initiate both a local response at the site of injury and a systemic response.

The cytokines produced by the infected epithelial cells, the intraepithelial lymphocytes, natural killer cells, the Polymorphonuclear Leukocytes (PMNs) and macrophages attracted to the infected site initiate the sequence of rolling followed by firm attachment and subsequent transmigration of circulating leukocytes into the infected tissue.

Role of Beta 2-Agonists in Chronic Airway Inflammation

Bacterial infections are common in the airways of patients with chronic lung diseases.[37-39] As many as 40% of stable asthmatics test positive for atypical bacteria in airway samples.[40] Higher levels of these pathogens such as *Mycoplasma pneumoniae* (Mp) and *Chlamydia pneumoniae* are associated with more severe asthma symptoms and increased COPD exacerbations.[41,42] Treatment with antibiotics, such as clarithromycin, can improve lung function in asthmatic patients with Mp.[43] However, bacterial infections remain prevalent in patients with chronic lung diseases, such as COPD, suggesting impaired lung host defense functions in these patients. Innate immune response in airway epithelial cells provides a vital source of host defense molecules to protect against respiratory colonization and infection.

Beta 2-agonists are the mainstay of therapy to induce bronchodilation in patients suffering from COPD and asthma. The drugs work through beta 2-adrenergic receptors to exert their functions, including relaxation in smooth muscle cells.[44] The receptors are expressed in various types of cells in the lung including airway epithelial cells.[45] In addition to their bronchodilatory effect, beta 2-agonists have been shown to reduce the production of inflammatory cytokines and thereby airway inflammation.[46] Moreover, beta 2-agonist salmeterol was shown to protect airway epithelial integrity that was otherwise impaired by *Pseudomonas aeruginosa* exoproducts.[47] Interestingly, activation of beta 2-adrenergic receptors on human peripheral blood T cells could modulate production of Th2 cytokines (e.g. IL-13).[48] Thus, beta 2-agonists exert an anti-inflammatory effect in chronic airway inflammation. These agents are also shown to cause apoptosis of virus-infected cells during an exacerbation leading to clearance of the airway bacterial load and controlling the infection. Extended use of exogenous antibiotics may cause drug resistance, thereby becoming less effective at eliminating chronic infections that are prevalent in COPD and asthma patients. Therefore, it is beneficial to enhance airway production of endogenous antimicrobial substances to promote the clearance of invading bacteria.

In conclusion, respiratory infections of the airway, either viral or bacterial, play a very important role not only in the pathogenesis and progression of the already burdened COPD, but acute and latent infections in COPD have a dramatic impact on the clinical course of COPD.

Treatment of Chronic Obstructive Pulmonary Disease

Peter J Barnes

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) is characterized in most patients by slow progressive development of airflow limitation that is not fully reversible.[1,2] COPD encompasses chronic obstructive bronchiolitis with obstruction of small airways and emphysema with enlargement of airspaces and destruction of lung parenchyma, loss of lung elasticity and closure of small airways.[3] Chronic bronchitis, by contrast, is defined by a productive cough of more than three months duration for more than two successive years; this reflects mucous hypersecretion and is not necessarily associated with airflow limitation. Most patients with COPD have all three pathological mechanisms (chronic obstructive bronchitis, emphysema and mucus plugging), but may differ in the proportion of emphysema and obstructive bronchitis. At present, these different phenotypes of COPD do not appear to affect the choice of therapy. However, in the future as more specific therapies are developed, careful phenotyping may be important in selecting optimal therapy.

Despite the enormous advances in asthma management that have taken place over the last 10 years, there have been relatively few new developments in the management of COPD. None of the existing drug therapies are able to significantly slow the relentless progression of airway obstruction, so treatment is based largely on improving lung function with bronchodilators, together with changes in lifestyle. Since the airflow obstruction in COPD is largely irreversible and current therapies do not alter the course of the disease, existing drug treatments provide only limited benefit to the patients. There is now an urgent search for the new classes of treatment that might alter the course of the disease in the future.

The management of COPD has now been formalized in guidelines produced in several countries and all propose escalating treatment, depending on the severity of airflow obstruction.[4]

RISK FACTORS AND THEIR PREVENTION

It is likely that there are important interactions between environmental factors and a genetic predisposition to develop the disease.

Environmental Risk Factors

In industrialized countries cigarette smoking accounts for most cases of COPD, but in developing countries other environmental pollutants, such as particulates associated with cooking with biomass fuels in confined spaces, are important causes.[5] Even in developed countries nonsmoking COPD may account for over 20% of COPD patients.[6] Much less is known about nonsmoking forms of COPD. Some cases are due to a progression of asthma, which loses its reversibility but these are usually identified by early onset and a typical history of variable symptoms at least in the early history of the disease. In developing and emerging countries, such as India exposure to biomass fuels is an important cause of COPD, especially in women, and accounts for over 50% of the cases.

Air pollution (particularly sulfur dioxide and particulates), exposure to certain occupational chemicals such as cadmium and passive smoking may all be additional risk factors. The role of airway hyperresponsiveness and allergy as risk factors for COPD is still uncertain. Atopy, serum Immunoglobulin E (IgE) and blood eosinophilia are not important risk factors. However, this is not necessarily the same type of abnormal airway responsiveness that is seen in asthma. Low birth weight is also a risk factor for COPD, probably because poor nutrition in fetal life results in small lungs, so that decline in lung function with age starts from a lower peak value. Poor nutrition may contribute to COPD and a lack of antioxidants may be particularly important.

Chest infections during the first year of life are associated with COPD in later life.[7] There is some evidence that certain latent virus infections (such as adenovirus) may predispose to the development of COPD, but this is controversial.[8] Many patients with COPD have a history of previous tuberculosis, whereas patients with COPD have an increased risk of developing Tuberculosis (TB), although the relationship between COPD and TB is not clear.[9]

The most important treatment strategy is the avoidance of environmental risk factors wherever possible to prevent disease progression. Most attention has focused on smoking cessation strategies.

Stopping Smoking

Stopping smoking is the single most beneficial management strategy and the only intervention that reduces the accelerated decline in lung function and the number of exacerbations and is important even in elderly patients (Fig. 83.1). Stopping smoking also reduces the mucus hypersecretion of chronic bronchitis and markedly reduces the risks of associated cardiovascular disease.[10] Smoking cessation is more effective early in the course of the disease and becomes less effective as the disease progresses to severe and very severe disease.[11]

Nicotine is addictive and stopping smoking should be viewed as the treatment of drug addiction. Abrupt quitting is more successful that gradual reduction, but even after an intensive smoking cessation program, 75% of smokers are still smoking one year later. There are several ways to encourage smoking cessation. Psychological counseling, group therapy and smoking reduction clinics may be useful in some patients. Nicotine replacement therapy doubles long-term (6–12 month) abstinence rates and is available as chewing gum, skin patches, nasal spray and inhaler.[13,14] Bupropion is an atypical antidepressant that acts through stimulating noradrenergic activity and has double the quit rate of nicotine replacement therapies.[15] More recently varenicline, which is a partial nicotinic agonist, has been introduced and shown to be the most effective way of quitting smoking.[16] Varenicline is usually given for 12 weeks and is well tolerated but some patients develop nausea and insomnia. Sometimes severe depression may also occur.

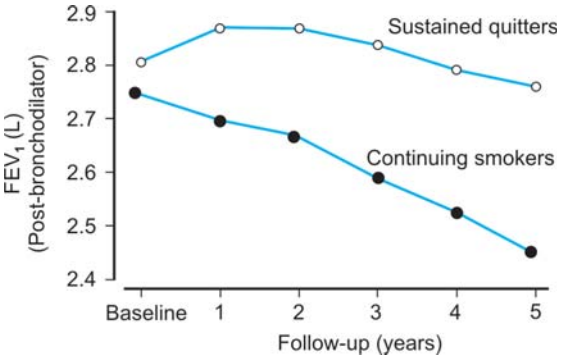

Fig. 83.1: Smoking cessation reduces the rate of decline of lung function in patients with COPD if instituted early in the course of the disease[12]

Avoiding Biomass Fuel Exposure

It is exposure to biomass fuels (wood, charcoal, animal dung) in unventilated houses which is a major risk factor for COPD in developing counties.[17,18] This may be addressed by using alternative fuels, such as Liquefied Petroleum Gas (LPG) or natural gas, ethanol or biogas, although this may not be available or affordable in poor rural communities. Improving ventilation of the cooking area, reducing cooking time or cooking outdoors may also help. Substitution of traditional open fires with locally produced improved stoves has been shown to improve respiratory health in women.

Genetic Factors

Longitudinal monitoring of lung function in cigarette smokers reveals that only a minority (15 to 40% depending on definition) develop significant airflow obstruction due to an accelerated decline in lung function (2- to 5-fold higher than the normal decline of 15 ml to 30 ml Forced Expiratory Volume in One Second (FEV_1) per year compared to the normal population and the remainder of smokers who have consumed an equivalent number of cigarettes.[19] This strongly suggests that genetic factors may determine which smokers are susceptible and develop airflow limitation. Further evidence that genetic factors are important is the familial clustering of patients with early onset COPD and the differences in COPD prevalence between different ethnic groups.[20]

Patients with alpha 1-antitrypsin deficiency [proteinase inhibitor (Pi) ZZ phenotype with alpha 1-antitrypsin levels less than 10% of normal values] develop early emphysema which is exacerbated by smoking, indicating a clear genetic predisposition to COPD. However, alpha 1-antitrypsin deficiency accounts for less than 1% of patients with COPD and many other genetic variants of alpha 1-antitrypsin that are associated with lower than normal serum levels of this proteinase inhibitor, have not been clearly associated with an increased risk of COPD. This has lead to a search for associations between COPD and polymorphisms of other genes that may be involved in its pathophysiology. So far, few significant associations have been detected and even those reported have not been replicated in other studies. A 10-fold increased risk of COPD in individuals who have a polymorphism in the promoter region of the gene for Tumor Necrosis Factor-Alpha (TNF-α) that is associated with increased TNF-α production has been reported in Chinese populations but not confirmed in Caucasian populations.

Several other genes have been implicated in COPD, but few have been replicated in different populations. Genome-wide association studies in COPD have found susceptibility related to two polymorphisms of the nicotinic receptor, which probably reflect propensity to nicotine addition.[21] It is unlikely that molecular genetics will identify new therapeutic targets. Even in patients with alpha 1-antitrypsin deficiency replacement therapy has been poorly effective as well as very expensive.[22] Techniques such as Deoxyribonucleic Acid (DNA) microarray (gene chips) to detect single nucleotide polymorphisms, proteomics to detect novel proteins and gene expression profiling to measure, which known and novel genes are expressed and are now being employed in cigarette smokers who develop COPD compared with matched smokers who do not. This may identify markers of risk, but may also reveal novel molecular targets for the development of treatments of the future.

Bronchodilators

Bronchodilators are the mainstay of current drug therapy for COPD, although the degree of bronchodilatation is less than seen in asthma (typically about 5% improvement in FEV_1, although some patients show greater responses). However, bronchodilators may improve dyspnea and exercise tolerance, despite little of no effect on spirometry, by reducing lung volumes and therefore hyperinflation (air trapping). In addition, bronchodilators may reduce respiratory muscle fatigue (controversial) and improve mucociliary clearance. The choice of bronchodilator includes short and long-acting beta-2 agonists, anticholinergics (muscarinic receptor antagonists) and high doses of theophylline and will partly be determined by patient preference and cost. The preferred bronchodilators are long-acting inhaled drugs such as Long-Acting Beta 2-Agonists (LABA, e.g. formoterol, salmeterol, indacaterol) or a Long-Acting Muscarinic Antagonist (LAMA, e.g. tiotropium bromide). Several bronchodilators are available for COPD (Table 83.1).

Anticholinergics

Atropine is a naturally occurring compound that was introduced for the treatment of asthma, but because of its side-effects (particularly drying of secretions); less

TABLE 83.1: Bronchodilators for COPD

Drug	*MDI (µg)*	*Nebulizer (mg)*	*Oral (mg)*	*Duration (hr)*
β_2-agonists				
Salbutamol	100-200	2.5-5.0	4	4-6
Terbutaline	250-500	5-10	-	4-6
Formoterol	12-24	-	-	12
Salmeterol	50-100	-	-	12
Bambuterol	-	-	10-20	
Anticholinergics				
Ipratropium	40-80	0.25-0.5	-	6-8
Oxitropium	200	-	-	7-8
Tiotropium	18	-	-	>24
Theophyllines				
Theophylline SR	-	-	200-400	12-24
Aminophylline SR			200-400	12-24

soluble quaternary compounds (e.g. ipratropium bromide) were developed. Anticholinergics are probably the most effective bronchodilators in the treatment of COPD and vagal cholinergic tone appears to be the only reversible element in the airflow obstruction of COPD. A small degree of resting bronchomotor tone is present because of tonic cholinergic nerve impulses, which release acetylcholine in the vicinity of airway smooth muscle, and cholinergic reflex bronchoconstriction may be initiated by irritants, cold air and stress (Fig. 83.2). Anticholinergics reduce air trapping by acting on small airways and thereby improve dyspnea and its symptoms.[23]

Ipratropium bromide and oxitropium bromide are administered three or four times daily via inhalation, whereas tiotropium bromide is given once daily by inhalation. Tiotropium is very effective in improving lung function and quality of life at all stages of the disease even when added to other therapies, as shown in the large UPLIFT study[24] (Fig. 83.3). Tiotropium also reduces severe exacerbations and hospital admissions, as well as mortality from COPD and cardiovascular disease.[24,25] Anticholinergic drugs may have additive bronchodilator effects with beta-2 agonists so may be given together. For short-acting drugs ipratropium-salbutamol inhalers are popular, whereas once daily combination inhalers containing tiotropium with formoterol are also available and in development.[26,27]

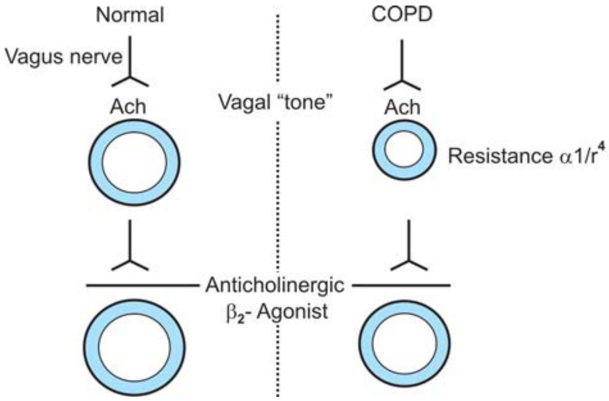

Fig. 83.2: Cholinergic control of airways in COPD. Normally there is a certain amount of cholinergic tone. This is exaggerated in COPD because of geometric factors related to the fixed narrowing of the airways (airway resistance R is proportional to $1/r^4$, where r is airway radius), so that airway resistance improves to a greater extent than in normal airways with an anticholinergic drug, which blocks the effect of acetylcholine (ACh) on muscarinic receptors in airway smooth muscle. Beta-agonists, which block all known bronchoconstrictor mechanisms, have a similar effect to anticholinergics suggesting that vagal tone is the only reversible component in COPD

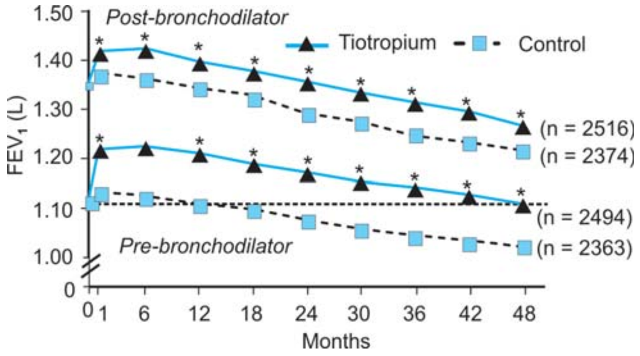

Fig. 83.3: The UPLIFT study. This large study of approximately 6,000 COPD patients compared tiotropium bromide (18 µg once daily) with placebo when added to current therapy. Tiotropium resulted in a greater increase in FEV_1 pre- and post-bronchodilator, which was sustained throughout the 4 years of the study[24]

Inhaled anticholinergic drugs are well tolerated, and systemic side-effects are uncommon because almost no systemic absorption occurs. Ipratropium bromide, even in high doses, has no detectable effect on airway secretions. Nebulized ipratropium bromide may precipitate glaucoma in elderly patients as a result of a direct effect of the nebulized drug on the eye; this is avoided by use of a mouthpiece rather than a face-mask. Dry mouth occurs in about 10% of the patients on tiotropium bromide but rarely requires discontinuation of treatment.

Beta-2 Agonists

Short-acting beta 2-agonists are used mainly for symptom relief as required but may be used four times a day on a regular basis. However LABA are preferred therapy for COPD as they give better control of symptoms and are used as a maintenance therapy.[28]

Beta-2 agonists have several beneficial effects on the airways in COPD (Fig. 83.4). These drugs act on airway smooth muscle causing a relaxation in large and small airways. They act as functional antagonists and reverse bronchoconstriction irrespective of cause. Experimentally, they reduce plasma exudation and cholinergic reflexes. They also increase mucociliary clearance (when it is reduced), but have no effect on chronic inflammation. Evidence suggests that beta-2 agonists may reduce adherence of bacteria to airway epithelial cells and this may reduce infective exacerbations.[29] There is some evidence that beta-2 agonists may increase the ventilatory drive to hypercapnia (but not to hypoxia).[30]

Side effects are not usually a problem and excessive use does not appear to be dangerous, even in patients with hypoxia and with cardiovascular disease. Muscle tremor,

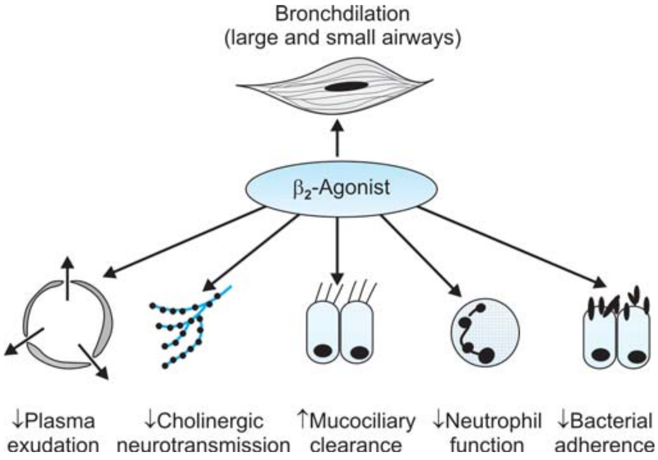

Fig. 83.4: Mechanism of action of beta-2 agonists in COPD. Although their primary action is likely to be on airway smooth muscle, there are additional effects of beta-2 agonists that may be beneficial

tachycardia, hypokalemia and restlessness are not uncommon. Occasionally hypoxemia may result from increased $\dot{V}/\dot{Q}$ mismatch due to pulmonary vasodilatation.

Short-Acting Beta 2-Agonists

Short-acting inhaled beta 2-agonists, such as salbutamol and terbutaline, are recommended for the immediate relief of symptoms. Ideally they should not be used regularly (as tolerance to their protective effects occurs), although in patients with severe COPD regular nebulized beta-2 agonists may be indicated.

Long-Acting Inhaled Beta 2-Agonists

Salmeterol and formoterol give bronchodilatation and protection against bronchoconstriction for over 12 hours[31,32] (Fig. 83.5). There is compelling evidence that these drugs are useful as bronchodilators in patients with COPD.[28] These drugs may improve symptoms, quality of life and exercise performance and reduce air through relaxant effects on small airways.[33] In long-term studies they are safe and reduce exacerbations and mortality[34,35] (Fig. 83.6). They have a similar efficacy to anticholinergics but together there may be additive effects. If the inhibitory effect of beta-2 agonists on bacterial adhesion is relevant *in vivo*, they may also reduce the frequency of infective exacerbations, although this has yet to be determined as there are no marked differences between LABA (salmeterol) and LAMA (tiotropium) in reducing severe exacerbations of COPD[25] (Fig. 83.7).

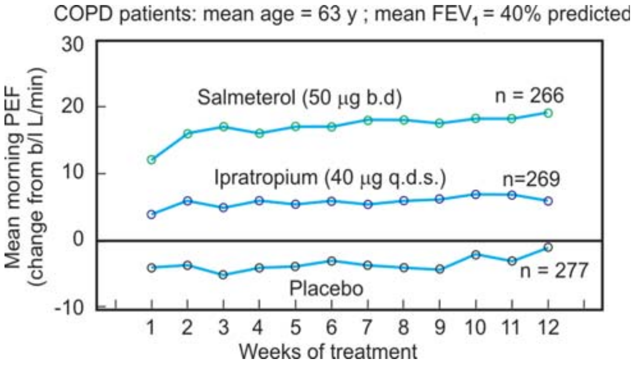

Fig. 83.5: The effect of salmeterol (50 µg BD) compared to ipratropium (40 µg GDS) in morning peak flow in patients with COPD[31]

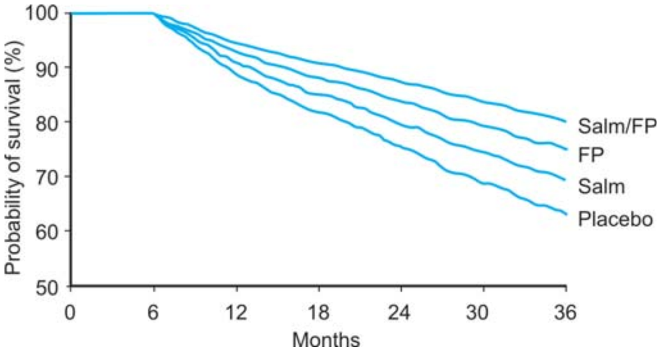

Fig. 83.6: TORCH study. This large study of approximately 6,000 COPD patients showed that fluticasone propionate/salmeterol reduced all cause mortality over 3 years, although this did not quite reach statistical significance (p = 0.052), whereas salmeterol and fluticasone alone had less effect[34]

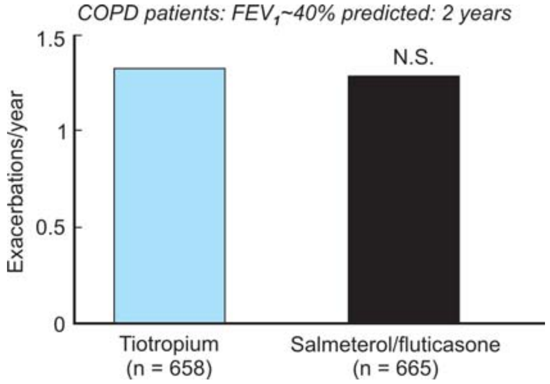

Fig. 83.7: Comparison between tiotropium and fluticasone/salmeterol in reducing acute exacerbations of COPD, showing no difference between these therapies[25]

Oral Beta-2 Agonists

Although inhaled beta-2 agonists are preferred, some elderly patients have problems with using inhalers. Slow-release oral beta-2 agonists preparations, such as bambuterol and slow-release salbutamol, are available. An advantage of these preparations is that they may treat peripheral airways more effectively, but the disadvantage is that the side effects are much more frequent than with inhaled preparations. Bambuterol is a prodrug which is slowly metabolized to terbutaline and is effective as a once-daily preparation in COPD.[36]

Theophylline

Theophylline in high doses (with plasma concentration 10 mg/l to 20 mg/l) is a useful additional bronchodilator in patients with severe COPD,[37] oral administration has the advantage of treating small airways.[38,39] It may have additional properties such as effects on mucociliary clearance and on respiratory muscles that are useful (Fig. 83.8). The major limitation to the use of theophylline is its side effects when high doses are used. More recently it has been established that lower doses of theophylline (plasma concentration 5 mg/l to 10 mg/l) have anti-inflammatory effects and specifically reduce neutrophilic inflammation in the airways of COPD patients.[40]

Theophylline acts through non-selective inhibition of phosphodiesterases, resulting in increased intracellular concentrations of Cyclic Adenosine Monophosphate (cAMP) and Cyclic Guanosine Monophosphate (cGMP). This effect is important for bronchodilator action, and might also be important in reducing neutrophilic inflammation. The drug also has some adenosine receptor antagonism, which accounts for some of the side effects, but there is little evidence that this is relevant for bronchodilator effects. Theophylline increases adrenaline secretion, but this is unlikely to account for the effects of the drug in COPD. Theophylline inhibits calcium entry and release and phosphoinositide hydrolysis. It is difficult to explain all of the beneficial effects of theophylline through these mechanisms alone, as many only occur at concentrations higher than those used therapeutically. More recently, it has been shown that low concentrations of theophylline are able to reverse corticosteroid resistance in COPD cells in vitro and preliminary studies have confirmed this in COPD patients.[41-43] This effect of theophylline is through direct inhibition of oxidative stress-activated phosphoinositide-3-kinase-δ, which results in increased histone deactylase-2 activity.[44]

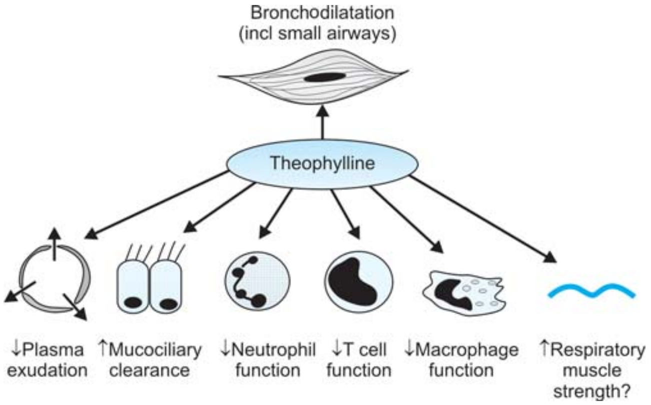

Fig. 83.8: Mechanism of action of theophylline in COPD. There may be several mechanisms of action of this drug, apart from bronchodilatation. At subbronchodilator doses theophylline reduces neutrophilic inflammation in COPD

Recommended Use in COPD: Theophylline is recommended as an additional bronchodilator in patients not controlled on regular inhaled anticholinergics and LABA. A slow-release preparation should be given twice daily to achieve plasma concentrations of 10 to 20 mg/l. The recent demonstration that theophylline has anti-inflammatory effects and reverses corticosteroid resistance in COPD may lead to the use of low doses (plasma concentration 1 to 5 mg/l) as a maintenance treatment combined with low doses of inhaled corticosteroids.[45,46] Low dose theophylline reduces exacerbations of COPD[47] and large trials studying the effects of low dose theophylline and inhaled or oral corticosteroids are needed.

Side effects are related to plasma concentration, although some patients may be particularly susceptible to side effects. They may be reduced by slowly increasing the dose when the drug is introduced. Side effects are mainly due to Phosphodiesterase (PDE) inhibition and include nausea and vomiting, headache, restlessness, gastroesophageal reflux, diuresis, cardiac arrhythmias (usually plasma concentration greater than 20 mg/l and due to adenosine receptor antagonism) and epileptic seizures (usually plasma concentration greater than 30 mg/l and due to adenosine receptor antagonism).

Clearance of Theophylline: The therapeutic effect is related to plasma concentration, which is affected by several factors that alter clearance (Table 83.2). If in doubt plasma concentrations should be measured.

Doxophylline

Doxophylline is a methylxanthine with similar bronchodilator properties to theophylline.[48] However, it

TABLE 83.2. Factors responsible for increased and decreased clearance of theophylline

Increased clearance (increase dose)
- Enzyme induction (rifampicin, phenobarbitone, ethanol)
- Smoking (tobacco, marijuana)
- Childhood
- High protein, low carbohydrate diet
- Barbecued meat

Decreased clearance (decrease dose)
- Enzyme inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, ketoconazole)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High carbohydrate diet

is not an adenosine receptor antagonist so there is reduced risk of cardiac arrhythmias or seizures. In addition there are fewer drug interactions.

Corticosteroids

The role of corticosteroids in the management of COPD remains controversial. Maintenance treatment with oral corticosteroids should be avoided as there is no evidence of benefit and a high risk of side effects in COPD populations. Inhaled corticosteroids are commonly prescribed in high doses on the basis that COPD is like poorly responsive asthma, but there is little evidence that they are beneficial in patients with pure COPD. Approximately 10% of the patients with COPD have a positive response to oral corticosteroids and it is likely that these patients have coexisting asthma and should therefore be treated as if they are asthmatic with regular inhaled corticosteroids. These patients may be recognized by increased eosinophils in the sputum.[49]

Patients with COPD have a poor response to corticosteroids in comparison to asthma with little improvement in lung function. High doses of inhaled corticosteroids have consistently been shown a reduction (20 to 25%) in exacerbations in patients with severe disease and this is the main clinical indication for their use.[4] However, several large studies have shown that corticosteroids fail to reduce the progression in COPD (measured by annual fall in FEV_1)[50] and they have not been found to reduce mortality in a large study.[34] These results are likely to reflect the resistance of pulmonary inflammation to corticosteroids in COPD patients as a result of the reduction in HDAC2.[51]

Side Effects

The reduction in the frequency of exacerbations, may be offset by systemic side effects such as osteoporosis, particularly in an elderly population that is may be poorly nourished with reduced mobility. There is evidence that high-dose inhaled corticosteroids are associated with increased cataracts in COPD patients.[52] Several large trials of high dose inhaled corticosteroids have shown an increase in reported pneumonia amongst COPD patients.[53] The role of inhaled corticosteroids in non-reversible COPD is therefore currently uncertain.[54] Lower doses of inhaled corticosteroids will have less risk of side effects and budesonide may be less likely to have adverse effects than fluticasone propionate.[55]

Combination Inhalers

Several studies have demonstrated a benefit of combination inhalers containing a corticosteroids and a LABA in COPD patients. However, most of the benefit is provided by the LABA component.[35] Any superiority of combination inhalers over LABA alone in reducing exacerbations may be counteracted by the higher risk of side effects due to the corticosteroids component.[56] Combination inhalers improve symptoms and reduce exacerbations with a reduction in all cause mortality, although this does not quite reach statistical significance[34] (Fig. 83.6). The reduction in exacerbation between twice daily fluticasone/salmeterol is similar to that seen with tiotropium[25] (Fig. 83.7). Combination inhalers may be useful when patients with FEV_1 less than 50% predicted and with frequent exacerbations (less than two per year) that are already in tiotropium need further treatment.

Supplementary Oxygen

Poor oxygenation is one of the fundamental problems of severe COPD and supplementary oxygen is an important part of therapy in patients with severe disease.[57] Controlled oxygen (24%) is used acutely in the treatment of acute exacerbations in all patients who are hospitalized. Long-Term Oxygen Therapy (LTOT, domiciliary oxygen) is indicated in selected patients with COPD. Two large multicenter trials demonstrated that long-term oxygen administration (less than 15 hours daily) prolong survival (by about 30%) in patients with COPD. The goal of oxygen therapy is to increase PaO_2 to above 60 mm Hg or an oxygen saturation of greater than 90%; increasing PaO_2 above 60 mm Hg has little further benefit and increases the risk of CO_2 retention.[58] There is a danger of inducing respiratory failure if supplementary oxygen is used in patients with CO_2 retention, so careful assessment is required before oxygen is prescribed.

Selection of Patients for LTOT

In some countries, guidelines (Department of Health) have been drawn up for the provision of LTOT. LTOT should not be considered in patients who continue to smoke. All patients should be assessed by a pulmonary specialist.

Absolute indications are as follows:

- Stable COPD with hypoxemia and edema
- FEV_1 <1.5 L, FVC <2.0 L
- PaO_2 <55 mm Hg (<7.3 kPa), $PaCO_2$ >45 mm Hg (>6 kPa)
- Stability demonstrated over three weeks on optimal therapy

Relative indications are as follows:

- As above but without edema or $PaCO_2$ >45 mm Hg
- Palliative (symptom relief)

Portable oxygen is indicated in patients who desaturate during exercise and its efficacy needs to be assessed during a treadmill or six-minute walk test with patients wearing portable oxygen cylinder. Portable oxygen may also be indicated in patients with severe exercise limitation irrespective of oxygen desaturation. Portable oxygen may also be needed in such patients during commercial airline flights (provided by airline).

Oxygen Supply

There are several ways of providing supplementary oxygen:

- *Compressed Gas Cylinders* containing 100% oxygen are inconvenient as regular delivery is needed and the cylinders are large and heavy, but is still the most widely used method in the United Kingdom. Fitted with flow meters that are either medium (2 l/min) or high (4 l/min).
- *Oxygen Concentrators* are the most economic and convenient way of delivering LTOT at home.[59]
- *Liquid Oxygen* is the most portable but most expensive form of supplementary oxygen. Lightweight devices weighing 3 kg can deliver oxygen for 14 hours at 2 l/min.

Oxygen may be delivered by several devices, which includes:

- *Face Masks:* Tight fitting masks are the most efficient devices, but are uncomfortable and inconvenient for long-term use.
- *Nasal Cannulae*: They are the most commonly used means of O_2 delivery and usually have no problems. A flow of 1.5 l/min to 2.5 l/min is usually adequate to achieve a PaO_2 greater than 60 mm Hg (more than 8 kPa).
- *Transtracheal Catheter:* Transtracheal Oxygen Therapy (TTOT) may be useful in some patients who cannot tolerate face masks or nasal cannulae, but catheters have to be removed and cleaned frequently.
- *Pulsed Delivery Systems:* They use a thermistor or pressure valve to deliver O_2 only during the beginning of inspiration. These devices are expensive but reduce the amount of oxygen used by over one-third.

Antibiotics

Since infection is often the cause of progression or acute deterioration in patients with COPD, the combating of infection by the appropriate use of antibiotics is an important part of therapy.[60] In fact, the organisms causing pulmonary infections are often the same as those found normally in the upper respiratory tract and it may be difficult to know if a pathogen isolated from the sputum is responsible for the exacerbation. For most of the time the sputum in COPD is mucoid but becomes yellow or green with the exacerbations of infection and when this occurs, it is usual to begin empirical antibiotic therapy. Purulence of sputum is due to an increase in degranulating neutrophils and may not necessarily imply bacterial infection. Indeed, many exacerbations of COPD are likely to be due to upper respiratory tract virus infections, such as *Rhinovirus*, *Coronavirus* and *Parainfluenza* virus.[61] This means that the antibiotics are often used inappropriately, but it is difficult to tell clinically whether an infection is viral or bacterial in origin. In a meta-analysis of placebo controlled trials of antibiotics for COPD there was a small but significant difference in Peak Expiratory Flow (PEF) between patients treated with antibiotics and placebo.[62]

The common bacterial organisms responsible for exacerbations of COPD, include *Streptococcus pneumoniae, Haemophilus influenzae* , *Moraxella catarrhalis*, *Mycoplasma pneumoniae* (less common). The choice of antibiotic depends upon the likely organisms, the likely sensitivity of the organisms in the community, the tolerance of the patient for the drug, the response to treatment. The treatment of choice in the community will often be either amoxicillin or co-trimoxamole (Septrin). Co-trimoxamole is not recommended as its usage leads to development of resistance and side effects due to the sulfonamide component commonly. However, because many strains of *H. influenzae* are now beta-lactamase producers and hence resistant to ampicillin/amoxicillin, the treatment for initial therapy commonly lies between:

- amoxicillin/clavulanic acid (Augmentin)
- erythromycin or other macrolides (clarithromycin, azithromycin)
- a cephalosporin, e.g. cefaclor
- a tetracycline, e.g. doxycycline

There are advantages and disadvantages to each drug and the choice may finally be based on finding out which drug works for a given patient. Cost is also a factor and there is no justification for using an expensive drug when a cheaper one works just as well. In most cases, the choice usually falls between amoxicillin, amoxicillin/clavulanic acid or doxycycline for the typical ambulatory patient.

The antibiotic should be given in full therapeutic doses for a course lasting about 10 to 14 days except for clarithromycin and azithromycin which are given for shorter periods (three days). Treatment is then stopped provided the patient has responded. If there has been a poor response a change of antibiotic may be indicated, usually to one of the newer broad spectrum agents such as clarithromycin if this has not already been tried. Continuous antibiotic administration is not recommended in COPD as this has not been shown to alter the course of the disease and is likely to lead to an increase in resistant organisms. Erythromycin has been shown to reduce exacerbations of COPD but it is not certain whether this is an antibiotic or an anti-inflammatory effect of the macrolide.[63]

OTHER DRUG THERAPIES

Mucolytics

Because mucus hypersecretion is a prominent feature of chronic bronchitis various mucolytic therapies have been used to increase the ease of mucus expectoration, in the belief that this will improve lung function.

- *Stopping Smoking* is the most effective way to reduce mucus hypersecretion.
- *Anticholinergics* may decrease mucus hypersecretion.
- *Beta-2 Agonists* and *theophylline* may improve mucus clearance.
- *Steam Inhalation* (with or without aromatics) may provide symptomatic relief, but there is no evidence that it improves lung function or long-term symptom control.
- Several drugs, such as *bromhexol* and *ambroxol*, reduce mucus viscosity in vitro, but there is little evidence from controlled trials that they improve lung function in patients with COPD, and cannot be recommended as routine therapy.
- Expectorants, such as *guaifenesin* and *potassium iodide*, similarly have no proven beneficial effects.
- *Recombinant Human DNAse* (alfadornase, Pulmozyme) has beneficial effects in some patients with cystic fibrosis, but its role in COPD is not yet clear. Until there is clear evidence of benefit in COPD it should not be used in view of its high cost.

Antioxidants

Since oxidant damage may be critical in the pathophysiology of COPD, antioxidant therapy is logical. *N*-Acetyl-Cysteine (NAC) and carbocisteine were originally developed as mucolytics, but have well documented antioxidant effects.[64,65] Although a meta-analysis of several small studies demonstrated a beneficial effect of NAC in reducing exacerbations of COPD by approximately 25%,[66,67] in a large prospective controlled trial NAC failed to reduce exacerbations, improve health status or reduce disease progression.[68] However, patients not already treated with inhaled corticosteroids obtained some benefit/ a large study from China showed that carbocisteine reduced exacerbations by approximately 25% over a year of therapy in treatment naïve patients.[69] This suggests that mucolytic/ antioxidants may be used in patients who are not already treated with inhaled corticosteroids and may provide benefit in reducing exacerbations.

Vaccines

- Influenza Vaccine is recommended as patients with COPD are subject to severe exacerbations with this infection and there if evidence for a reduction in acute exacerbations and hospital admissions. There is convincing evidence that influenza vaccination is cost-effective in elderly people and should be more so in patients with COPD. Influenza vaccination reduces all cause mortality in COPD patients.[70] Influenza vaccination should be given prior to the winter season.
- Polyvalent pneumococcal vaccine is used in many countries to protect against the development of pneumococcal lung infections. Pneumococcal vaccination is cost-effective, but does not reduce mortality[70] and there are no convincing large trials to show a reduction in exacerbations.[71] Improved vaccines are now in development.
- Broncho-Vaxom (OM85-BV) is a mixture of bacterial products that activate macrophage function (the advantage of which is obscure). There is some evidence that it may reduce the severity of acute exacerbations, but it cannot be recommended as a routine treatment.[72]

Neuraminidase Inhibitors

Inhibitors of neuraminidase, such as zanamivir (inhaled) and oseltamivir (oral) speed the recovery from influenza. However, there are no specific trials in patients with COPD and it is not yet certain whether this treatment is cost-effective.[73]

Treatment of Dyspnea

Breathlessness is a problem in many patients, particularly "pink puffers." Several drugs, including nebulized opiates, slow-release morphine, dihydrocodeine and benzodiazepines, may reduce the sensation of dyspnea but the reduction in ventilatory drive is potentially dangerous and these drugs should be avoided, particularly during exacerbations.[74]

Respiratory Stimulants

There is no role for respiratory stimulants, such as doxapram or almitrine, in the long-term management of COPD, since there is no evidence that central ventilatory drive is impaired. Ventilation is limited by mechanical rather than neurophysiological factors. However, doxapram may be indicated in the management of an acute exacerbation of COPD if there is hypercapnia and hypoventilation in order to tide the patient over 24 to 36 hours until the underlying cause (e.g. infection) is controlled. However, it is likely that the use of doxapram in this situation will decline as Nasal Intermittent Positive Pressure Ventilation (NIPPV) becomes more widely available.

Antitussives

Cough is often a troublesome symptom of COPD, but may have a protective effect in clearing secretions. The regular use of antitussives is therefore not recommended in COPD.[75,76]

NON-PHARMACOLOGICAL TREATMENTS

Several non-pharmacological approaches have also been used in the management of COPD and may form part of a comprehensive rehabilitation program in elderly patients.

Exercise

Exercise training to improve cardiorespiratory function may be helpful; the type of exercise does not appear to be important and aerobic exercise or upper limb exercises are equally effective. Respiratory muscle training using resistive inspiratory loading may reduce breathlessness, but a meta-analysis of controlled studies of respiratory muscle training alone has provided no evidence of overall benefit.[77] Controlled breathing techniques, such as pursed-lip breathing and diaphragmatic breathing, result in reduced dyspnea, particularly in patients with hyperventilation.

Nutrition

Nutrition is important in patients with COPD as many of them are malnourished and underweight, although marked cachexia is now uncommon. Several patients with COPD are obese because of reduced physical activity. They should lose weight, particularly if they have sleep disturbances, metabolic syndrome or frank type II diabetes. Antioxidant vitamin supplements should also be indicated. However, there is no convincing evidence that improved nutrition and nutritional supplements with a high fat content that are marketed for use in COPD are beneficial in these patients.[78,79] The place of androgens and anabolic steroids to build muscle bulk in COPD has not been established.[80]

Pulmonary Rehabilitation

Rehabilitation concerns prevention of deconditioning and allowing the patient to cope with his/her disease. Rehabilitation programs are successful in prospective randomized trials in the terms of increased performance and quality of life, even though they may not improve lung function.[81] Patients with moderate-to-severe COPD should be considered for pulmonary rehabilitation programs, which include educational advice and physiotherapy. There is evidence that pulmonary rehabilitation also increases the efficacy of bronchodilator therapy.[82]

Artificial Ventilation

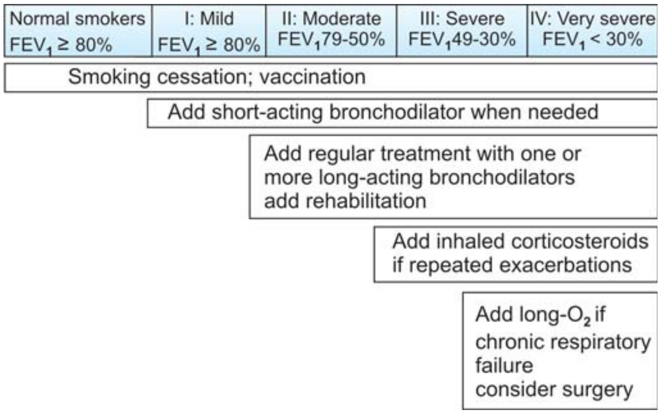
Artificial ventilation devices have improved enormously. Non-invasive ventilation using nasal intermittent positive pressure ventilation has been an important advancement in the management of acute exacerbations of COPD in hospital and more recently for the control of hypercapnic respiratory failure at home, thus reducing the need for hospitalization.[83] Nasal intermittent positive pressure ventilation corrects the hypercapnia and respiratory acidosis, while resting the respiratory muscles. Good results in the management of acute exacerbations have been reported, with significant reduction in mortality and time spent in hospital.[84]

Surgery

Several surgical techniques have been successfully applied to more severe emphysema. These include heart-lung transplantation, now largely replaced by single-lung transplantation in carefully selected patients.[85] Lung volume reduction surgery (LVRS) by excision of badly affected emphysematous lung is effective in highly selected patients with bilateral predominantly upper lobe emphysema and evidence of air trapping. There is sustained improvement in lung function and reduction in symptoms with a reduction in exacerbations.[86] Patients with a very poor diffusing capacity had an increased mortality. Therefore, patient selection is very important.[87] More recently bronchoscopic lung volume reduction surgery has been developed to avoid the surgical morbidity and mortality of LVRS. Several devices, including valves, coils and irreversible non-blocking techniques (bronchoscopic thermal vapor ablation, polymeric lung volume reduction) designed to collapse and remodel hyperinflated lung are currently in development.[88]

MANAGING CHRONIC DISEASE

It is important that an accurate diagnosis is made and that COPD is differentiated from asthma, which is usually possible from the history. Spirometry is important to diagnose airway obstruction objectively and to stage the disease in order to decide on the most appropriate therapy. In the Global initiative for chronic Obstructive Lung Disease (GOLD) Guidelines for COPD treatment of chronic disease follows a stepwise escalation based on disease severity[4] (Fig. 83.9). At all stages smoking cessation is important, particularly in the early stages of disease and patients should routinely receive immunization against seasonal influenza. In GOLD stage 1 there is usually little functional impairment and the only treatment needed is short-acting bronchodilator such as salbutamol, ipratropium or a combination of the two to be inhaled as required. In patients with GOLD 2, the preferred therapy is a long-acting bronchodilator—either tiotropium once daily or salmeterol or formoterol twice daily. Patients often prefer the once daily regime. If long-acting bronchodilators are too expensive it may be necessary to use a short-acting bronchodilator, such as salbutamol or ipratropium bromide, regularly four times daily or an oral bronchodilator, such as slow-release theophylline twice daily or bambuterol once daily. Sometimes it is necessary to use a combination of long-acting anticholinergic and LABA and a combination inhaler is preferred. For GOLD 3 patients, an inhaled corticosteroid may be added and this is often done by using a combination inhaler with a steroid and LABA. Oral theophylline may also be added at this stage as it may have an anti-inflammatory effect. Pulmonary rehabilitation is also useful is some patients if it is available. In GOLD 4 patients, it is necessary to consider the use of supplementary oxygen and for much selected patients lung surgery.



Normal smokers
$FEV_1 \geq 80\%$
I: Mild
$FEV_1 \geq 80\%$
II: Moderate
$FEV_1$79-50%
III: Severe
$FEV_1$49-30%
IV: Very severe
$FEV_1 < 30\%$
Smoking cessation; vaccination
Add short-acting bronchodilator when needed
Add regular treatment with one or more long-acting bronchodilators add rehabilitation
Add inhaled corticosteroids if repeated exacerbations
Add long-O_2 if chronic respiratory failure consider surgery

Fig. 83.9: Stepwise treatment of COPD as described in the GOLD initiative[89]

TREATMENT OF ACUTE EXACERBATIONS

An important aim of treatment is to prevent exacerbations. Several of the treatments for chronic diseases have been shown in controlled trial to reduce exacerbation rates and hospitalization, including long-acting bronchodilators (both beta-2 agonists and anticholinergic), low-dose theophylline, high-dose inhaled corticosteroids and smoking cessation.

Chronic obstructive pulmonary disease exacerbations are one of the commonest causes of hospital admission. Apart from the treatment of underlying bacterial infection with antibiotics (as discussed above), exacerbations are treated symptomatically by increasing the dose of SABA and anticholinergic bronchodilators delivered by nebulizer. The place of antibiotics is not certain as controlled trials show little clinical benefit; this may reflect the fact that over half of the exacerbations are due to viral or non-infective causes. Oxygen (24% or 28% via Venturi mask) should be given to achieve a PaO_2 of at least 60 mm Hg without a fall in pH to less than 7.26 (indicating an acute change). Blood gases should be checked within one hour of starting oxygen therapy. Oxygen saturation by pulse oximetry may be used to monitor response providing $PaCO_2$ and pH are normal. A course of oral corticosteroids is usually indicated but only reduces in-patient stay by about one day.[90] Very high does of corticosteroids, such as intravenous methylprednisolone, are not required as there is a greater risk of side effects.[91] Diuretics are indicated if there is peripheral edema. Chest physiotherapy may be useful, although there is no evidence from controlled studies that it improves recovery. Development of respiratory failure with a rising $PaCO_2$ may necessitate NIPPV or intubation.

TREATMENT OF COR PULMONALE

Cor pulmonale (right heart failure) is due to the effect of chronic hypoxia on the pulmonary vasculature resulting in pulmonary hypertension. It is usual to treat with LTOT. Diuretics are used to reduce fluid retention. Digoxin is only indicated if there is coexistent atrial fibrillation. Vasodilators may be hazardous as they lower systemic as well as pulmonary blood pressure.

FUTURE THERAPIES

There is a pressing need to develop new therapies, as existing treatments do not alter the progressive course of the disease or reduce mortality. There have been relatively few advances in the therapeutic options for the treatment of COPD, but better understanding of the molecular mechanisms involved in the pathogenesis of COPD will undoubtedly lead to improved therapies in the future.[92,93]

Several inhaled long-acting bronchodilators are currently in clinical development for COPD. Once daily inhaled beta-2 agonsits, including indacaterol, carmoterol, GW642444 and BI-1744, are in clinical development for COPD.[94] Indacaterol, if taken once daily, shows good efficacy in COPD with a similar sustained increase in FEV_1 as with tiotropium.[95] Several once daily anticholinergics, including glycopyrrolate, aclidinium and darotropium, are also in clinical development. Combination inhalers that contain a LABA and a LAMA, such as QVA149, show additivity and may be the most useful bronchodilators in the future for patients with more severe COPD.

There are currently no treatments, apart from theophylline, that reduce inflammation in COPD and there is an intense search for drugs that are effective against steroid-resistant inflammation. Drugs that block specific mediators, such as leukotriene B_4 and tumor necrosis factor, have not been shown to have any benefit. Phosphodiesterase 4 (PDE4) inhibitors have a broad spectrum of anti-inflammatory effects and are very effective in animal models of COPD. A PDE4 inhibitor, roflumilast, has been shown to significantly increase FEV_1 and reduce exacerbations, but these effects are really small and are not accompanied by any improvement in symptoms or health status.[96,97] The major problem with these drugs is the side effects due to PDE4 inhibition, which include nausea, headaches and diarrhea, and these limit the dose that can be given by mouth. There are now attempts to develop inhaled PDE4 inhibitors to avoid these side effects. Several other anti-inflammatory drugs are also in clinical development, including p38 MAP kinase inhibitors and Nuclear Factor Kappa-light-chain-enhancer of activated B cells (NF-κB) inhibitors, but these drugs also have side effect issues and may need to be given by the inhaled route.

Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Raja Dhar, AG Ghoshal

INTRODUCTION

Chronic Obstructive Pulmonary Disease (COPD) exacerbation occurs despite adequate control. Most patients experience episodes of exacerbation at least one or more times during their life-time and many suffer with these episodes at least one to three times a year. These episodes may vary immensely in the terms of frequency and severity. Chronic obstructive pulmonary disease exacerbations have a huge impact on the overall health condition of the patient, both physically as well as emotionally. Moreover, exacerbation costs a huge amount of money to the patient and the family. A moderate exacerbation, not requiring ventilation (with or without hospitalization) will cost around Rs 8,000 (approximate costs based on local data.) It must be remembered that even in patients with stable COPD, a severe exacerbation episode can cause a significant dent in pulmonary function and adversely affect the quality of his/her life. It is therefore extremely important for practicing physicians to learn the early identification of crisis, perform optimal management under appropriate settings, escalate and de-escalate the therapy based on patient's response, bring back the patient to the initial baseline status, help the patient and family to cope up with the situation with adequate support, discharge the patient in a stable clinical conditions, give necessary instruction about the proper follow-up.

Thankfully, with modern evidence-based treatment modalities, successful management of COPD exacerbation can be done in the majority of patients.

COPD EXACERBATION

An exacerbation of COPD is an event in the natural course of COPD characterized by an acute change in the patient's baseline dyspnea or breathing difficulty, cough and/or sputum production beyond day-to-day variability sufficient to warrant a change in management.

It can be infective or noninfective in nature. In the absence of a universal agreed criterion, the following operational classification can help to rank the clinical severity of the episode and its outcome.

- Level I: Treated at home
- Level II: Requires hospitalization
- Level III: Leads to respiratory failure

Causes of COPD Exacerbations

About 50% of COPD exacerbations are caused by lower respiratory tract infections, while the remaining are caused by exposure to indoor or outdoor air pollutants, changes in weather and several host factors including peer compliance to therapy (Table 84.1).[1,2]

Symptoms of COPD Exacerbation

Usually patients present with one or more symptoms of acute exacerbation (Table 84.2). During clinical assessment, further objective evaluation is necessary. Several clinical elements must be considered when evaluating patients with exacerbations. These include the assessment of the severity of the underlying COPD, the presence of comorbidities and the history of previous exacerbation. The physical examination

TABLE 84.1: Causes of COPD exacerbations

Infectious process	Viral (Rhinovirus spp., influenza); Bacterial *(Haemophilus influenzae, Streptococcus pneumoniae, Moraxella catarrhalis,* Enterobacteriaceae species, *Pseudomonas* spp.)
Environmental conditions	Sudden change in temperature, humidity, etc, air pollution exposure, exposure to tobacco smoke, noxious gases or irritating chemicals
Host factors	Patients with poor general health condition, poor nutritional status, immune-compromised status, lack of compliance with prescribed medical therapy, adoption of unhealthy lifestyle modes like lack of continuing with advised exercises, improper diet, poor level of personal hygiene, lack of compliance with long-term oxygen therapy, failure to participate in pulmonary rehabilitation

should evaluate the effects of the episode on hemodynamic and respiratory systems. The diagnostic procedures to perform such as chest radiography, sputum and blood examination and spirometry would depend on the clinical setting of the evaluation.[3,4]

Management of COPD Exacerbation

The decision to treat a patient at home or in the hospital is based both on subjective evaluation as well as objective criteria (Table 84.3). The choice of the patient/patients‘ family should also be taken into account.

However, it must be noted that there may be a sudden deterioration of condition and the decision to treat at home or at hospital can change rapidly (Table 84.4).

Development of new situations may warrant further evaluation and subsequent hospitalization.

Diagnosis of an exacerbation is primarily clinical and dependent on investigation though they are useful in assessing the severity and planning the optimum treatment (Table 84.5).

TABLE 84.2: Symptoms of COPD Exacerbation

- Increase in cough
- Chest pain
- Increase in breathlessness
- Increase in sputum volume and change in its colour (white to green, yellow or blood streaked)
- Fever
- Increased tiredness
- Increase in oxygen requirement (for those on long-term oxygen therapy)

Primary Care

In patients with an exacerbation managed in primary care:

- Sending sputum samples for culture is not recommended in routine practice.

TABLE 84.3: Clinical factors that determine whether the patient should be treated at home or hospital

Factor	*Indication to treat at home*	*Indication to treat at hospital*
Able to cope at home	Yes	No
Severity of breathlessness	Mild	Severe
General health condition	Good/Satisfactory	Poor/deteriorating
Level of activity	Good	Poor/confined to bed
Cyanosis	No	Yes
Worsening peripheral edema	No	Yes
Level of consciousness	Normal	Impaired
Already receiving LTOT	No	Yes
Social circumstances	Good/adequate support	Living alone/not coping
Acute confusion/altered mental status	No	Yes
Rapid rate of onset	No	Yes
Significant comorbidity (particularly heart disease and insulin-dependent diabetes)	No	Yes
SaO_2 <90%	No	Yes
Changes on the chest radiograph	No	Present
Arterial pH level	$\geq$ 7.35	< 7.35
Arterial PaO_2	$\geq$ 7 kPa	< 7 kPa

TABLE 84.4: The situations for immediate reassessment of the patient condition

- Marked increase in dyspnea
- Inability to eat or sleep due to respiratory symptoms
- Inadequate response to the outpatient management
- Worsening of hypoxemia
- Worsening of hypercarbia
- Change in mental status
- Poor perception of severity
- Inability of the patient to take care of himself/herself/lack of home support
- Documented noncompliance to prescribed therapy
- Development of new symptoms
- Uncertain diagnosis

- Pulse oximetry may be useful if there are clinical features of a severe exacerbation.

Patients Referred to Hospital

In all patients with an exacerbation referred to hospital:

- A chest radiograph should be obtained.
- Arterial blood gas tensions should be measured and the inspired oxygen concentration recorded.
- An ECG should be recorded to exclude cardiac comorbidities.
- A full blood count should be performed; urea and electrolyte concentrations should be measured.
- A theophylline level should be measured in patients who are on theophylline therapy at admission.
- If sputum is purulent, a sample should be sent for microscopy and culture.
- Blood cultures should be taken if the patient has fever.

Outpatient Management for COPD Exacerbation (Level I)

The treatment of exacerbation has to be based on the clinical presentation of the patient.

The essential components of treatment are shown in Table 84.6.

TABLE 84.5: Elements of the clinical evaluation and diagnostic procedures that are usually informative in patients with exacerbations according to the severity of the episode

	Level I (Treated at home)	*Level II (Requires hospitalization)*	*Level III (Leads to respiratory failure)*
Clinical history			
Comorbid conditions *	+	+++	+++
Frequent exacerbations	+	+++	+++
Severity of COPD	Mild/Moderate	Moderate/Severe	Severe
Physical Findings			
Hemodynamics	Stable	Stable	Stable/unstabe
Use of accessory muscles while breathing/tachypnea	Not present	++	+++
Persistent symptoms after initial therapy	No	++	+++
Diagnostic Procedures			
Oxygen saturation	Yes	Yes	Yes
Arterial blood gases	No	Yes	Yes
Chest radiograph	No	Yes	Yes
Blood tests†	No	Yes	Yes
Serum drug concentration§	If applicable	If applicable	If applicable
Sputum gram stain and culture	No ¶	Yes	Yes
Electrocardiogram	No	Yes	Yes

Keys:

***** the more common comorbid conditions associated with poor prognosis in exacerbations are congestive heart failure, coronary artery disease, diabetes mellitus, renal and liver failure

† Blood tests include cell blood count, serum electrolytes, renal and liver function

§ Consider if patients are using theophylline, warfarin, carbamezepine, digoxin

¶ Consider if patient has been recently on antibiotics

+ unlikely to be present

++ likely to be present

+++ very likely to be resent

TABLE 84.6: The essential components of treatment of COPD exacerbation

Bronchodilators
- Short-acting beta 2-agonist***** and/or ipratropium by metered dose inhaler with spacer or hand-held nebulizer as needed.[5-7]
- Consider adding long-acting bronchodilator, e.g. formoterol [by Metered-Dose Inhaler (MDI) plus spacer or nebulized route] if patient is not using it

Corticosteroids (the actual dose may vary)
- Oral prednisone 30–40 mg per os q.d. for 10 days[8-10]
- Consider using an inhaled corticosteroid[11]

Antibiotics[1,12-17]
- May be initiated in patients with altered sputum characteristics
- Choice should be based on local bacteria resistance patterns
- Amoxicillin/ampicillin†, cephalosporins§
- Doxycycline
- Macrolides¶[18-20]
- If the patient has failed prior antibiotic therapy consider: Amoxicillin/clavulanate[19]
  Respiratory fluoroquinolones******[13,21,22]
- Cefdinir, Cefprozil, Cefuroxime

Patient Education
- Check inhalation technique
- Consider use of spacer devices

Keys: Metered-dose inhaler*****: salbutamol/levosalbutamol, terbutaline; †: depending on local prevalence of bacterial beta-lactamases; §: cefpodoxime, cefprozil, cefuroxime, Cefdinir; ¶: azithromycin, clarithromycin, dirithromycin. roxithromycin; ******: gatifloxacin, levofloxacin and moxifloxacin.

Inpatient Management of COPD Exacerbation (Level II and III)

As mentioned earlier, the decision to admit a patient is derived from the subjective interpretation of clinical features, such as the severity of dyspnea, determination of respiratory failure, short-term response to emergency room therapy, degree of cor pulmonale and the presence of complicating features such as severe bronchitis, pneumonia or other comorbid conditions.

Very few clinical studies have investigated patient-specific objective clinical and laboratory features that identify patients with COPD who require hospitalization. General consensus supports the need for hospitalization in patients with severe acute hypoxemia or acute hypercarbia. Less extreme arterial blood gas abnormalities, however, do not assist decision analysis. Other factors that identify "high-risk" patients include a previous emergency room visit within seven days, the number of doses of nebulized bronchodilators, use of home oxygen, previous relapse rate, administration of aminophylline and the use of corticosteroids and antibiotics at the time of previous emergency room discharge.[23-26]

Pharmacologic management remains the mainstay of COPD exacerbation along with other supportive measures.

Inhaled Bronchodilators

- Short-acting beta 2-agonist (salbutamol 100–200 mcg inhaler/levosalbutamol) and/or
- Ipratropium MDI (20, 40 mcg) with spacer or hand-held nebulizer as needed.[5-7]

Delivery systems for inhaled therapy during exacerbations
- Both nebulizers and hand-held inhalers can be used to administer inhaled therapy during exacerbations of COPD.
- The choice of delivery system should reflect the dose of drug required, the ability of the patient to use the device and the resources available to supervise the administration of the therapy.
- If a patient is hypercapnic or acidotic, the nebulizer should be driven by compressed air, not oxygen (to avoid worsening hypercapnia). If oxygen therapy is needed, it should be administered simultaneously by nasal cannulae.
- The driving gas for nebulized therapy should always be specified in the prescription.

Systemic Corticosteroids

- Inhaled corticosteroids by MDI or hand-held nebulizer should be considered.[11] For example: Beclomethasone 50–400 mcg; Budesonide 100, 200, 400 mcg; Fluticasone 50–500 mcg inhaler.
- In the absence of significant contraindications, oral corticosteroids should be used in conjunction with other therapies in all patients admitted to hospital with an exacerbation of COPD.
- In the absence of significant contraindications, oral corticosteroids should be considered in patients managed in the community who have an exacerbation with a significant increase in breathlessness which interferes with daily activities.
- Patients requiring corticosteroid therapy should be encouraged to present early to get maximum benefits.
- Prednisolone 30 mg orally should be prescribed for 7–14 days.
- If patient tolerates, prednisone 30–40 mg per day should be prescribed for 10 days.[8-10]
- If patient cannot tolerate oral intake, consider equivalent dose intravenous (IV) for up to 14 days (20 mg hydrocortisone is equivalent to 5 mg prednisolone, 4 mg methylprednisolone and 0.75 mg dexamethasone).

- It is recommended that a course of corticosteroid treatment should not be longer than 14 days as there is no advantage in prolonged therapy.
- Osteoporosis prophylaxis should be considered in patients requiring frequent courses of oral corticosteroids.
- Patients should be made aware of the optimum duration of treatment and the adverse effects of prolonged therapy.
- Patients, particularly those discharged from hospital, should be given clear instructions about why, when and how to stop their corticosteroid treatment.

Antibiotics[1,2,9-19,23,27]

Antibiotics based on local bacteria resistance patterns should be started for patients with the history of producing purulent sputum. Any change in sputum characteristics like color, consistency and volume should also prompt the initiation.

- Antibiotics need not be started for patients having exacerbations without increase in sputum purulence, unless there are signs of consolidation on chest radiograph or clinical symptoms of pneumonia.
- Antibiotic choice should be based on local bacteria resistance patterns, if available. However, when this information is not available, macrolides or second generation cephalosporins can be used.

  Initial empirical treatment should consist of an aminopenicillin, a macrolide or a tetracycline. When initiating empirical antibiotic treatment, one should always take account of any guidance issued by the local microbiologists.
- When sputum has been sent for culture, the sensitivity to antibiotics should be checked to ensure appropriate therapy.
  - Amoxicillin/clavulanate[19] and respiratory fluoroquinolones (levofloxacin, moxifloxacin)[13,21,22] are commonly used.
  - If *Pseudomonas* spp. and/or other *Enterobacteriaceae* spp. are suspected, consider combination therapy [e.g. Piperacillin/tazobactam (3.375 g q 4 hours IV) or imipenem (500 mg q 6 hours IV) or meropenem (1 g q 8 hours IV) plus Amikacin (7.5 mg/kg q 12 hours or 15 mg/kg q 24 hours IV) or Levofloxacin (500 mg daily) for 10–14 days].

Theophylline and Other Methylxanthines

- Intravenous theophylline should only be used as an adjunct to the management of exacerbations of COPD if there is an inadequate response to nebulized bronchodilators.
- Care should be taken when using intravenous theophylline because of its interactions with other drugs (e.g. ciprofloxacin, clarithromycin, allopurinol, phenytoin, etc.) and potential toxicity if the patient has been on oral theophylline.
- Within 24 hours of starting the treatment, the theophylline levels should be monitored to maintain within therapeutic range (10–20 mcg/ml). Thereafter, monitoring should be done as frequently as indicated by clinical circumstances.

Respiratory Stimulants

It is recommended that doxapram is used only when noninvasive ventilation is either unavailable or considered inappropriate (e.g. hypersensitivity, pulmonary embolism, severe hypertension, cerebral edema, epilepsy, hyperthyroidism, etc.).

Oxygen Therapy

Oxygen therapy is recommended to relieve severe respiratory distress and prevent tissue hypoxia.

- The goal is to prevent tissue hypoxia by maintaining arterial oxygen saturation (SaO_2) at more than 90%
- All patients with COPD exacerbation should have their arterial oxygen tension (PaO_2), arterial carbon dioxide tension ($PaCO_2$) and pH measured upon admission, during the course of treatment and whenever there is any change in patient's clinical condition.
- In case of unavailability of arterial blood gas measurement facility, oxygen saturation should be measured. Pulse oxymeters should be available to all health care professionals managing patients with exacerbations of COPD and they should be trained in their use. Clinicians should be aware that pulse oximetry gives no information about the PCO_2 or pH.
- Even if oximeter is not available for any reason, oxygen should be given to all patients with an exacerbation of COPD who are breathless, even if the oxygen saturations are not known, but careful monitoring of the patient condition is essential to prevent excessive CO_2 washout and cause respiratory depression since CO_2 acts as the respiratory drive for many COPD patients.
- The principal delivery device for oxygen comprises of nasal cannula and venturi mask. Alternative delivery devices include non-rebreather mask, reservoir cannula or transtracheal catheter.
- During the transfer to hospital, the following points should be considered:

  - It is not desirable to exceed an oxygen saturation of 93%. Oxygen therapy should be commenced at approximately 40% and titrated upwards if saturation falls below 90% and downwards if the patient becomes drowsy or if the saturation exceeds 93% to 94%.
  - Patients with known type II respiratory failure need special care, especially if they require a long ambulance journey or if they are given oxygen at home for a prolonged period before the ambulance arrives. It is important to remember that the prevention of tissue hypoxia supercedes CO_2 retention issue.
- The aim of oxygen therapy during exacerbation of COPD is to maintain adequate level of oxygen (SaO_2 >90%) without worsening or precipitating respiratory acidosis or worsening hypercapnia. If pH falls below 7.35 (acidemia), consider mechanical ventilation.

Admission to Intensive Care Unit (ICU)/ Critical Care Unit

The decision to shift/admit a patient to the critical care unit largely depends on subjective assessment and clinician's judgment, although various diagnostic parameters help in decision making. Presence of the following features merit consideration for shifting to Intermediate Respiratory Care Unit (IRCU):

- Persistent respiratory distress despite standard management.
- Inability to maintain oxygen level above 90% despite oxygen therapy by high-flow mask.
- Persistent hypercapnia.
- Abnormal blood gas parameters (PaO_2 <60 mm Hg and/or $PaCO_2$ >60 mm Hg).
- Alteration of mental status, acute confusion, drowsiness.
- Increased signs of infection (pyrexia, increased sputum purulence/volume, etc.).
- Significant abnormal changes in chest radiograph.
- Clinical deterioration.

ASSISTED VENTILATION

Despite optimal pharmacologic management, severe cases of exacerbation necessitates ventilatory support, when the patient is unable to maintain the breathing function and/or unable to maintain sufficient gaseous exchange for normal physiologic function.

Ventilatory support, either "invasive" or "non-invasive," is not a therapy but a form of life support until the cause of underlying acute respiratory failure is reversed with medical therapy.[28-30]

Noninvasive Ventilation

Noninvasive ventilation is an alternative for patients who have respiratory failure and can no longer breathe on their own. It enhances the breathing process by giving the patient a mixture of air and oxygen from a flow generator through a tightly fitted facial or nasal mask. Noninvasive ventilation assists the patient in taking a full breath and helps to maintain an adequate oxygen supply to the body.[31] Noninvasive Positive Pressure Ventilation (NIPPV) is by far the most popular mode of providing noninvasive ventilation[30,32] in combination with some Continuous Positive Airway Pressure (CPAP) plus Pressure Support Ventilation (PSV).[28,33]

It improves the gas exchange by improving the alveolar ventilation, without causing significant modifications in the alveolar ventilation/perfusion mismatching and gas exchange in the lungs.[34] The application of the combination of CPAP and PSV offers a better outcome than either alone because the CPAP counterbalances the intrinsic positive end expiratory pressure.[35]

Noninvaisive Ventilation (NIV) should be used as the treatment of choice for persistent hypercapnic ventilatory failure during exacerbations despite optimal medical therapy. Noninvasive positive pressure ventilation should be offered to patients with exacerbations when, after optimal medical therapy and oxygenation, respiratory acidosis (pH <7.36) and or excessive breathlessness persist. All patients considered for mechanical ventilation should have arterial blood gases measured.

- If pH <7.30, NIPPV should be delivered under controlled environments such as intermediate ICUs and/or high-dependency units. If pH <7.25, NIPPV should be administered in the ICU and intubation should be readily available.
- It is important to ensure that the NIV be administered by a dedicated team by its staff, with necessary training for the same, well conversant with its application as well as the limitations.
- The combination of some CPAP (e.g. 4–8 cm H_2O) and PSV (e.g. 10–15 cm H_2O) provides the most effective mode of NIPPV.
- NIV should also be a consideration for patients who are slow from weaning from ventilator. (Factors influencing slow weaning are not provided in guideline).

- The combination of some CPAP (e.g. 4–8 cm H_2O) and PSV (e.g. 10–15 cm H_2O) provides the most effective mode of NIPPV.
- In the first few hours, the level of assistance and monitoring of NIPPV is same as mechanical ventilation.
- When put on NIV, there should be a well-defined plan for every patient on course of action on deterioration as well clear indicators of the limits of such deterioration, when the next action is to be taken.

Clinical Settings

NIPPV can be delivered in different clinical settings which are as follows:

- Medical ward: Patients with moderate acidosis (pH 7.30–7.35) and hypercapnia (6–8 kPa ($PaCO_2$ 45–60 mm Hg).[36,37]
- Intermediate or high-dependency respiratory unit[38,39] patients who present moderate-to-severe acidosis (pH <7.30); the facilities for rapid endotracheal intubation and institution of conventional mechanical ventilation should be promptly available.
- ICU:[40] Patients with severe respiratory acidosis (pH <7.25); in this particular setting, NIPPV may be as effective as conventional mechanical ventilation to reverse acute respiratory failure due to COPD.[41]

It is important to note that the one-year mortality was reported to be lower in patients receiving NIPPV for exacerbations of COPD, compared to both optimal medical therapy alone[42] and conventional mechanical ventilation.[41]

Mechanical Ventilation

Mechanical ventilation is a mode of assisted or controlled ventilation using mechanical devices that cycle automatically to generate airway pressure.[43] Intubation should be considered in patients with the following:

- *NIPPV failure:* Worsening of arterial blood gases and or pH in one to two hours; lack of improvement in arterial blood gases and or pH after four hours.
- *Severe acidosis* (pH <7.25) and hypercapnia [$PaCO_2$ >8 kPa (60 mm Hg)].
- *Tachypnea* >35 breaths/minute.
- *Other complications:* Metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, massive pleural effusion.[40]
    - During exacerbations of COPD, functional status, body mass index, requirement for oxygen when stable, comorbidities and previous admissions to ICUs should be considered, in addition to age and Forced Expiratory Volume in One Second (FEV_1), when assessing suitability for intubation and ventilation. Neither age nor FEV_1 should be used in isolation when assessing suitability.
    - Noninvasive positive pressure ventilation should be considered as the first-line intervention, in addition to optimal mechanical therapy, for the management of patients with respiratory failure due to exacerbation of COPD.[32] In the first few hours, NIPPV requires the same level of assistance as conventional mechanical ventilation.[44]
    - The fact that NIPPV is cost-effective is clearly demonstrated by a study[21,45] and it can also be used as a potential successful strategy of weaning[22,46] the patients from mechanical ventilation, in cases where the patients need an intermediate care between complete machine-dependent and totally independent for breathing.
    - The NIPPV may also be considered for those with history of previous persistent weaning failure.[47]

De-escalation of Therapy

- Patients' recovery should be monitored by regular clinical assessment of their symptoms and observation of their functional capacity.
- For patients with nonhypercapnic failure, nonacidotic failure can be monitored with pulse oximetry.
- For hypercapnic or acidotic patients, intermittent blood gas monitoring should be done to evaluate the situation. The frequency of such tests largely depends on the clinical judgment of the treating physician.
- During recovery from an exacerbation from COPD, daily performance of FEV_1 or peak expiratory flow is not advised since the magnitude of change is small as compared to the variability of measurement.

Discharge should be planned when:

- There is significant improvement in the clinical status of the patient.
- Significant improvement of symptoms like breathlessness, cough, remission or steady improvement in infection symptoms (reduction in sputum volume, non-pyrexial status, nonpurulence of sputum as confirmed by culture).
- Ability to maintain blood gas at acceptable range.
- Ability and inclination to perform day to day activities, even with some degree of assistance.

On the other hand of the spectrum, discharge or hospice care needs to be planned when the patient has already reached the end-stage and no significant improvement in clinical and cognitive status is unlikely.

- Spirometry measurement is a must for all patients before discharge. This helps in assessing the impact of the exacerbation episode on the pulmonary function and reassign the baseline values, in case of any alteration.
- Patients should be re-established on their optimal maintenance bronchodilators.
- Patients and/or home carers must be given the necessary information so that they fully understand the correct usage of medication including oxygen (if applicable).
- Follow-up visits must be scheduled and communicated to the patient/family.
- Follow-up care like refilling of medication, visiting nurse, oxygen delivery and referral for other support must be made before discharge.
- Before the patient is discharged, the patient, family members and the treating physician must be confident that the patient will be able to manage successfully. In case of doubts, formal assessments can be initiated.
- All aspects of the routine care that patients receive (including appropriateness and risk of side effects) should be assessed before discharge.
- It is useful to hand over a written plan on daily self care, medication management, emergency action plan during exacerbation to all patients/carers before discharge, with adequate explanation.

Long-term Oxygen Therapy

R Agarwal, SK Jindal

Long-term Oxygen Therapy (LTOT) is now a popular mode of therapy for a variety of respiratory disorders. When LTOT at home was first introduced, it was largely limited to patients with Chronic Obstructive Pulmonary Disease (COPD) and chronic respiratory insufficiency.[1-3] Subsequently, the indications continued to expand to include almost any chronic respiratory disease characterized by hypoxemia. In fact domiciliary oxygen is also useful in those patients who do not demonstrate hypoxemia such as those with breathing disorders during sleep or exercise. Hypoxemia in such patients is absent when they are alert and awake, but gets precipitated during sleep or exercise. Some of the common conditions for which LTOT has been used with variable degrees of benefit include COPD, interstitial lung disease, bronchiectasis, cystic fibrosis, kyphoscoliosis, sleep apnea syndrome, severe cardiac failure and other causes of chronic breathlessness.[4-15] More important than the underlying disease are the other selection criteria required to be fulfilled for LTOT.

SELECTION OF PATIENTS[5,16,17]

All patients with chronic hypoxemic lung disease are potential candidates for LTOT. Following guidelines are used to select patients for instituting the treatment.

i. A definitive documented diagnosis responsible for chronic hypoxemia.
ii. An optimal medical treatment should be in effect.
iii. Patient in a stable condition.
iv. Oxygen administration should have been shown to improve hypoxemia and provide clinical benefit.

It is important to ensure that the patient is compliant with the general medical regimen and follows instructions, such as to quit smoking. Continued smoking not only aggravates the disease process but also reduces the full physiological benefits of oxygen and poses inherent safety risk of accidental fires.

Following specific indices are used while prescribing long-term oxygen:

i. At rest, in non-recumbent position the PaO_2 of 55 mm Hg or less.
ii. Patients with PaO_2 of more than 55 mm Hg are considered in the following conditions:
   a. Patient on optimal medical treatment, with demonstrable hypoxic organ dysfunction, such as secondary pulmonary hypertension, cor pulmonale, polycythemia or central nervous system dysfunction.
   b. When there is a demonstrable fall in PaO_2 below 55 mm Hg during sleep, associated with disturbed sleep pattern, cardiac arrhythmias or pulmonary hypertension. These patients may be benefited by nocturnal oxygen therapy.
   c. When there is demonstrable PaO_2 fall during exercise and oxygen administration is shown to improve exercise performance, duration or capacity. These patients may benefit by oxygen during exercise. They may also be administered supplemental oxygen before and after the exercise.

It is important to mention that PaO_2 (of 55 mm Hg or less) is not the only guide to prescribe oxygen. It is the presence of a chronic hypoxemic pulmonary disease.

Healthy people living at an altitude of 10,000 feet or more do not require oxygen. They are able to acclimatize to even severe degrees of hypoxemia. In fact man has survived without oxygen even at the top of Mount Everest (altitude 29,028 ft). It is a patient with a chronic pulmonary disease who loses the ability to adapt and requires long-term oxygen therapy.

BENEFITS[5,16-20]

Long-term oxygen therapy is definitely shown to benefit patients with COPD (Table 85.1). It has been used in other chronic pulmonary hypoxemic diseases as well, however with limited experience. In COPD, it improves survival, and the quality of life. Exercise tolerance is increased and cognitive mental function improved. Some other conditions, where LTOT has been used, include idiopathic pulmonary fibrosis, severe heart failure, extensive bronchiectasis and severe kyphoscoliosis. In the authors' experience, its use in chronic interstitial pulmonary fibrosis and respiratory insufficiency was associated with signficant reduction in breathlessness and overall comfort. There was an appreciable reduction in pulmonary hypertension and right ventricular failure attributable to supplemental domiciliary oxygen therapy when added to the optimal medical regimen.

Indications

Stable Chronic Obstructive Lung Disease[16-23]

There is evidence in literature to support the role of long-term domiciliary oxygen therapy in stable COPD; however, the role of oxygen therapy in patients who have only nocturnal hypoxemia or hypoxemia during exercise only, is logical but not well supported by evidence from the literature.

TABLE 85.1: Benefits of long-term oxygen therapy

1. Improvement in duration of survival
2. Improved intellectual function
3. Pulmonary hypertension: Decrease in pulmonary vasoconstriction and vascular resistance. This improves the severity of right heart failure.
4. Decrease in red cell mass and hematocrit level. Complications of polycythemia are therefore diminished.

Potential benefits

- i. Increased exercise ability
- ii. Improved quality of life – patients resuming gainful employment and participating in their own care more actively
- iii. Decrease in dyspnea
- iv. Decrease in hospitalization and exacerbations of respiratory failure
- v. Delayed development of cor pulmonale.

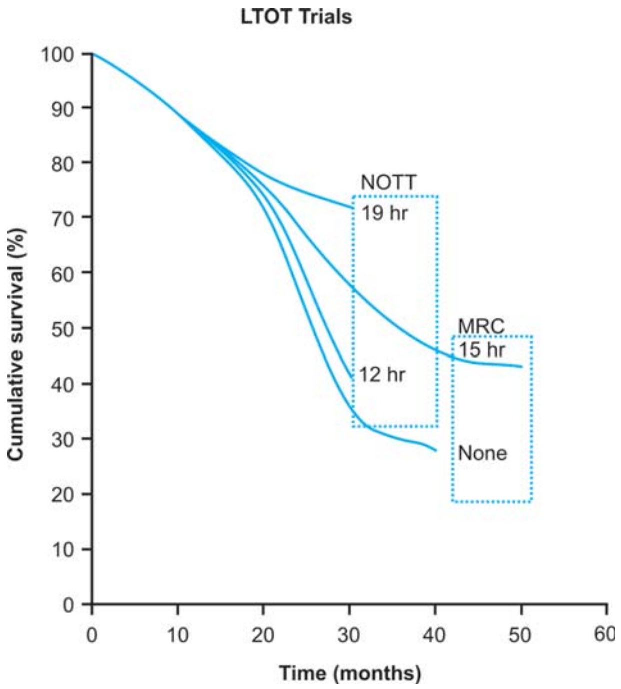

Fig. 85.1: Graph showing increased survival in patients receiving LTOT

1. *Long-term oxygen therapy in patients who have daytime resting hypoxemia:* Two landmark studies, i.e. the Medical Research Council (MRC) trial and the Nocturnal Oxygen Therapy Trial (NOTT) have shown that continuous long-term oxygen therapy can improve survival in patients with COPD and resting daytime hypoxemia (Fig. 85.1). The results of both the randomized controlled trials are summarized below:

Nocturnal Oxygen Therapy Trial (NOTT)[2]

A total of 1,043 patients from six centers in the United States were screened for inclusion in the study. Only 203 patients were finally included; others were excluded because of many reasons, including major concomitant diseases and patients who had previous oxygen therapy or PaO_2 greater than 59 mm Hg. The study was not blinded.

One hundred and two patients with hypoxemic COPD were randomly allocated to nocturnal oxygen therapy and 101 to continuous oxygen therapy. The oxygen source was an oxygen concentrator, liquid oxygen or compressed gas (flow 1-4 LPM). The mean age was 65.7 years in the nocturnal oxygen therapy group and 65.2 years in the continuous oxygen therapy group. Most patients were male, 80.4% in the nocturnal oxygen therapy group (82% used oxygen for 13 hours or less) and 77.2% in the continuous oxygen therapy group (56% used oxygen for 19 hours or more). The mean PaO_2, $PaCO_2$, Forced Expiratory Volume in One Second (FEV_1), were 51 mm Hg, 43 mm Hg and 29% respectively, and were not different between the two groups.

There was a significant difference in survival in favor of the continuous oxygen therapy group, and the overall mortality in the nocturnal oxygen therapy group was 1.94 times that of the continuous oxygen therapy group. The continuous oxygen therapy group also showed improvement in stroke volume index, pulmonary vascular resistance and pulmonary artery pressure but not in other hemodynamic parameters compared to nocturnal oxygen group.

Medical Research Council (MRC) Oxygen Therapy Trial[3]

Eighty-seven patients with a diagnosis of COPD with hypoxemia (PaO_2 40 to 60 mm Hg) and right failure were randomized to receive continuous oxygen therapy (15 hours a day) or no oxygen. The study was not blinded. The treatment group received oxygen therapy for at least 15 hours a day at a flow-rate of a minimum of 2 LPM. The mean age, FEV_1, PaO_2, $PaCO_2$, were around 58 years, 0.7 liters, 50 mm Hg and 54 mm Hg respectively. There was an improvement in survival in the group receiving oxygen therapy (Peto Odds ratio 0.42, 95% CI 0.18 to 0.98) but only beyond 500 days of treatment. Although, the mortality was improved in female patients for the oxygen-treated group from the commencement of treatment, the numbers were too small for any meaningful interpretation. Although the total pulmonary resistance and the pulmonary artery pressure increased in the control group, this was not statistically significant but suggests benefit from oxygen therapy.

Data from these two trials clearly showed that there was a survival benefit with continuous oxygen therapy but none with nocturnal oxygen therapy alone. Recent studies have also shown that LTOT can decrease hospitalization in patients with COPD. Importantly, oxygen should be taken for as long as possible as hypoxemia related pulmonary vascular changes could occur rapidly. In fact there is some data to show that these changes can occur in less than three hours. The current widely accepted indications for LTOT in COPD are summarized below:

Indications for oxygen therapy in patients with chronic obstructive pulmonary disease:

- $PaO_2 \leq 55$ mm Hg
- PaO_2 56-59 mm Hg plus either pulmonary hypertension or hematocrit ≥ 55%.

On the other hand, there is no justification for the prescription of LTOT in patients with mild hypoxemia defined as PaO_2 between 56 to 65 mm Hg. In a recent study by Gorecka et al, 135 patients with COPD who had severe airflow limitation (FEV_1 less than one liter) with PaO_2 of 56 to 65 mm Hg, were randomly allocated to a control (n = 67) or LTOT (n = 68) group. The patients were followed every three months for at least three years or until death. There were no significant differences in survival rates between patients treated with LTOT and controls, nor did longer oxygen use (over 15 hours per day) improve outcome. Younger age, better spirometric values, and higher body mass index predicted better survival. It can be therefore concluded that domiciliary oxygen treatment does not prolong survival in patients with COPD and moderate hypoxemia. It is the airway limitation which seems to determine survival in this group of patients.

Initiation and reassessment of LTOT: Patients with COPD who have FEV_1 less than 40% and/or pulmonary hypertension should be routinely screened for LTOT. Before prescribing LTOT, the indication should be confirmed on at least two occasions two to three weeks apart with a resting arterial blood gas analysis performed on room air. Patient should be stable on maximal and optimal medical therapy including a complete pulmonary rehabilitation program. Smoking cessation should be strictly enforced. The oxygen flow rate should be set to maintain a PaO_2 greater than 60 mm Hg during waking and at rest; usually 1 to 2 LPM through nasal prongs would generally suffice. The oxygen flow rate should be increased by 1 LPM during sleep, exertion and air travel.

The goal of LTOT should be confirmed by performing an arterial blood gas analysis after one to two months of initiating oxygen therapy, and documenting a PaO_2 greater than 60 mm Hg; a repeat blood gas analysis also helps in assessment of the hypercapnic response to oxygen therapy. Patients with significant hypercapnia with oxygen therapy may also require domiciliary noninvasive pressure support ventilation.

2. *Oxygen therapy in patients who have no daytime resting hypoxemia but develop hypoxemia during sleep:* The role of oxygen therapy, in patients who have no daytime hypoxemia but are hypoxemic during sleep only, is controversial. Patients with COPD can experience prolonged episodes of oxygen desaturation during rapid eye movement sleep, and studies have shown that

nocturnal hypoxemia can exacerbate pulmonary hypertension in patients with COPD, but recent studies have challenged this finding. Although it seems logical to administer oxygen in patients with nocturnal hypoxemia, the current literature does not support this fact. Data is insufficient to make general recommendations, and further studies are needed. The current practice is to rule out concomitant obstructive sleep apnea in patients with COPD and those who have got nocturnal symptoms, and to intensify medical management (smoking cessation, inhaled corticosteroids, long-acting β_2 agonists and anticholinergic agents, pulmonary rehabilitation) if the patient is found to have nocturnal hypoxemia without daytime hypoxemia. Oxygen therapy in this subgroup of patients may be indicated, if the patient has evidence of chronic hypoxia-related sequelae like polycythemia or pulmonary hypertension. Another subgroup of patients whose oxygen saturation repeatedly falls below 88% for more than one-third of the night may also benefit from nocturnal oxygen therapy.

3. *Oxygen therapy in patients who have no daytime resting hypoxemia but develop hypoxemia during exercise:* Intermittent oxygen therapy can be used in patients for indications described above, where the benefits of LTOT are well known. The benefits of pulmonary rehabilitation on exercise capacity and quality of life in COPD patients support the use of ambulatory oxygen in all patients on LTOT to allow them to achieve their full potential in the terms of reduced mortality from continuous oxygen therapy. The role of intermittent ambulatory oxygen therapy in patients, who do not fulfill the criteria for LTOT, is controversial.

There is evidence to show an improved exercise tolerance and improved quality of life in patients who use intermittent oxygen therapy prior to exercise. On the other hand, some studies do not show significant benefit. There are some studies, which have shown benefit even with room air itself, and the hypothesis is that the cold effect of the air probably helps in the resolution of dyspnea. Thus, the evidence from the available literature is inadequate on the role of intermittent oxygen therapy, and more studies are required to amicably solve this issue.

In the absence of any definite data, intermittent oxygen therapy may be prescribed in individual patients in whom the benefits (dyspnea, exercise capacity) have been definitely proven by an exercise test (complete incremental exercise testing, six-minute walk test, shuttle test) especially in those patients awaiting lung transplantation or lung volume reduction surgery, to maintain an increased level of fitness prior to surgery.

In conclusion, oxygen therapy in COPD has several definite benefits such as improvement in survival, improvement in intellectual functioning, decrease in pulmonary vascular resistance and pulmonary arterial pressure, decrease in red cell mass and diminution in the complications of polycythemia; other potential benefits include increased exercise capacity, decrease in dyspnea, improved quality of life and decrease in hospitalization. In view of these benefits, oxygen therapy now occupies a key role in the long-term management and rehabilitation of patients with COPD.

Acute Exacerbations of COPD[24-27]

Patients of COPD often have chronic hypoxemia with or without CO_2 retention. An acute exacerbation of airway obstruction, mostly occurring after a respiratory tract infection causes worsening of hypoxia. Oxygen in this situation is required until the exacerbation is settled. While a high FiO_2 of up to 50% can be initially administered in case hypoxemia is severe, it is soon tapered to around 24 to 30% FiO_2. The goal of supplemental O_2 is to maintain a PaO_2 of 55 to 60 mm Hg which corresponds to SpO_2 of about 90%.

Higher concentration of oxygen blunts the hypoxic ventilatory drive, which may precipitate hypoventilation and CO_2 retention. It is not uncommon for CO_2 narcosis to occur following excessive concentrations of FiO_2. A recent study on 65 patients admitted with acute COPD exacerbations showed that a majority of patients who achieved a PaO_2 greater than or equal to 74.5 mm Hg compared with those with a PaO_2 less than 74.5 mm Hg had a longer hospital stay, more frequent admission and the greater use of noninvasive ventilation. It is better to use a regulated flow device such as a ventimask, which guarantee oxygen delivery to a reasonable extent. Once the patient is stabilized, one can shift to nasal prongs—a device which is more comfortable and acceptable to the patient.

Oxygen Prescription

Most of the COPD patients are prescribed low flow concentrations at 1 to 2 l/min. Higher flow rates are required for some of the patients, especially those with other chronic respiratory diseases. The treatment is guided by PaO_2 which should be maintained at 60 mm Hg or so (SaO_2 of 85 to 90%). During the period of exercise, sleep or other activities, the flow rate may be increased by another 1 to 2 l/min. While continuous therapy is required for patients who show hypoxemia at rest, intermittent treatment during specific periods may be used for patients who demonstrate intermittent hypoxemia.

Supply Sources[28-32]

There are three main types of systems commercially available for the supply of oxygen at home: Compressed gas cylinders, liquid oxygen and oxygen concentrators.

Compressed Gas Cylinder

The commonly used gaseous system in the home consists of H or K cylinders containing compressed oxygen. A pressure regulator and a flowmeter are required to adjust the amount delivered to the patient. When continuously used at 2 l/min, each cylinder will last for about two and half days necessitating frequent fillings. They are also heavy giving an unsightly look to the bedroom. Moreover, regulation of pressure and flow require some effort and additional help. For the present, compressed gas cylinders are most commonly used for domiciliary use in India. It is because of its lower costs and relatively easy availability in even small towns compared to the other systems. Gas cylinders also form a good back up facility in case of a failure of other systems. Portable D and E cylinders are available for ambulatory use. Aluminum cylinders are also available. These are lighter in weight than the cast iron cylinders. They are better suited for portability, but are costlier.

Liquid Oxygen System (LOX)

The LOX system for use at home is a smaller version of the bulk liquid system used in the hospitals. The reservoir (stationary) unit contains about 70 to 90 pounds of oxygen in the liquid state at –273ºF. It lasts for 4.5 to 10 days at a continuous flow rate of 2 l/min. The vessel is about 3 to 4 feet tall and about 18 inches in diameter. The internal pressure is about 22 to 50 psi which can generate flow rates of 0.25 to 15 l/min. In addition to the stationary unit, there is a light weight portable unit which can be carried by the patient on the shoulder for ambulatory and outdoor activities. The portable units are designed to be filled from the stationary reservoir unit with safety.

There is a minor loss of gaseous oxygen from the liquid gas units at a rate of about 1 lb/day. Therefore, the units should not be stored in a small and closed space to avoid gaseous accumulation posing a fire hazard.

Liquid gas system is more practical but expensive. It is not easily available in this country as yet.

Oxygen Concentrator

It is an electrical device that provides oxygen from the atmospheric air. It employs a molecular "sieve" that filters out the nitrogen molecules, water vapor and other trace gases. It can deliver 85 to 90% oxygen at flow rates of up to 4 l/min. The polymeric membrane concentrators can deliver 30 to 40% oxygen at flow rates of up to 10 l/min.

A concentrator is ideal for use at home. It obviates the need of regular filling of the tank. Its initial cost is high but the running cost is negligible. Proper maintenance of equipment and replacement of filters is required. A back up source of oxygen supply (e.g. compressed oxygen cylinder) is necessary in case of a power failure.

There is generation of some noise and heat that some patients may find bothersome. This can be avoided by placing the concentrator in an adjacent room and using a longer oxygen tube. This may increase the back pressure necessitating the use of a pressure compensated flowmeter to assure accurate oxygen flow.

Delivery Devices[31,32]

Devices used to deliver oxygen include cannulae, prongs and masks. Those are essentially the same as used in the hospitals. Nasal cannulae and prongs are preferred because of the cosmetic reasons. It is easy to conceal oxygen tubing by applying it to ordinary thick rimmed frames of eye-glasses ("Oxyspecs"). Different kinds of "Oxyspecs" and other devices are now commercially available for this purpose. There is no difference in the type of delivery devices used with different types of oxygen sources.

Humidification is not essential at flow rates of less than 4 l/min unless the patient complains of dryness of the nose or mouth, nasal irritation or crusting. Humidifier is a potential source of infection and needs regular cleaning and disinfection. Disposable humidifiers significantly increase the costs.

Oxygen-conserving Devices[33-35]

Oxygen therapy on long-term basis is a costly proposition. Many patients tend to conserve oxygen by reducing the flow as well as the duration of administration. Moreover, the standard oxygen supply devices allow the flow of oxygen both during inspiration and expiration. In fact it is only 15 to 20% part of respiratory cycle during inspiration which delivers the oxygen to the alveoli effectively. A lot of oxygen delivered to the patient is therefore, wasted in the surroundings.

Several methods have been devised to conserve oxygen in the recent years. It is possible to save up to 50% oxygen with some of these methods. There are three types of devices commercially available for this purpose.

i. *Reservoir oxygen delivery:* With this method, oxygen which is stored during exhalation in a reservoir (approximately 20 ml) becomes available at the beginning of inhalation. There are two types of reservoir cannulae in use:

Pendant reservoir (Oxymizer pendant): The reservoir coupled to the nasal prongs consists of a collapsing chamber that hangs at the chest. It saves oxygen between 2:1 and 4:1 over continuous flow oxygen therapy.

"Moustache configured" oxymizer: The reservoir sits right on the face thus being noticeable and cosmetically unsightly. Its efficiency is similar to that of pendant reservoir.

Both the reservoirs provide equivalent oxygen saving at flow rates of 0.5 l/min. But the Pendant reservoir can be operated at 0.25 l/min to achieve the oxygen saturation similar to those of a flow of 1 l/min with a steady flow delivery system. The reservoirs maintain a saving of 3:1 to 4:1 over steady flow during exercise as well.

Recently, a pendant which allows pursed lip breathing has been described. It combines oxygen saving mechanism of the Pendant with that of pursed lip breathing. It increases the efficiency of oxygenation to about 7:1 compared with standard steady flow systems.

ii. *Electromechanical pulsing devices:* The electromechanical demand devices deliver oxygen only during inhalation. Delivery of oxygen during exhalation is saved. It consists of a box shaped unit attached to the outlet of the oxygen source and a solenoid valve which opens on sensing the decrease in pressure as the patient inhaled. A "pulsed" volume of 15 to 35 ml of oxygen is delivered each time. It reduces the amount of oxygen usage by 35 to 75% producing a saving of about 7:1 compared with continuous flow system.

Electronic demand devices are also available for use with portable cylinders as well as with piped-in-oxygen system in the hospitals. Some of the demand devices available in the Western market include Pulsair, DO2S, Oxymatic, etc. They significantly add to the costs and produce a "clicking" sound at the bed side. Both these factors make it unacceptable to many of the patients.

iii. *Transtracheal catheters:*[35] It is a narrow lumen catheter which resembles an angiocatheter. It is inserted directly into the trachea. Oxygen is delivered through a tubing attached to a small fitting at the neck. There are several reasons to believe that it is more effective:

- Oxygen is delivered ahead of the nasopharynx bypassing some of the anatomical dead space.
- The upper airways serve as a reservoir towards the end of expiration.
- The oxygen delivered is not diluted with atmospheric air prior to entering the respiratory tract.

Transtracheal catheters are useful for patients receiving very high liter flows. They save oxygen by an efficiency factor of 2:1 to 3:1. Its efficiency can be further enhanced by combining it with pulsed oxygen delivery. Intratracheal catheter is more acceptable to the patient since the look is not unsightly. There is nothing on the face and it can be easily hidden beneath the collars. Moreover, there is no nasal or auricular irritation; it does not get dislodged during sleep.

There is a small risk of infection and subcutaneous emphysema when the catheter is introduced. It can get plugged with mucus and thick secretions. It should therefore be cleaned on daily basis. Patients with transtracheal catheters should have conventional cannulae at home for use in an emergency when the transtracheal catheter gets blocked due to kinking or plugging.

Some of the transtracheal catheters available commercially are Heimlich MicroTrach, the SCOOP catheter and the Intratracheal Oxygen Catheter (ITOC). The ITOC is implanted through a subcutaneous tunnel from the chest wall to the trachea. It is of more permanent nature.

Risks of Long-term Oxygen Therapy[36-41]

There are three types of risks associated with long-term use of oxygen: Physical, functional and cytotoxic.

i. *Physical risks:* Since oxygen supports combustion, the tanks are potential risks of fire hazard and tank explosion. In fact these risks are rather small. It is highly desirable that smoking is stopped with its use. The supply source (such as a cylinder) should not be kept in a small closed room to avoid accumulation of the vented gas.

The other minor risks of oxygen therapy include the injury to the nose and face from catheters and masks. Dryness and crusting may occur from dry, non-humidified gas.

ii. *Functional risks:* Oxygen therapy may accentuate hypoventilation in patients with COPD. This may induce hypercapnia and carbon dioxide narcosis. In practice, with low-flow oxygen therapy, the risk is rather small.

Therefore, chronic carbon dioxide retention is not considered a contraindication for long-term oxygen therapy. It has been suggested that arterial pH is a better guide to monitor therapy than $PaCO_2$. Patients with carbon dioxide retention also tolerate and benefit from long-term oxygen as long as pH does not show acidemia.

iii. *Cytotoxic damage:* Long-term oxygen can cause structural damage to the lungs. Both proliferative and fibrotic changes of oxygen toxicity have been shown at autopsy on COPD patients treated with long-term oxygen. But there is no significant effect of these changes on clinical course or survival of these patients. Most of the structural damage attributable to hyperoxia results from high FiO_2 administration in acute conditions.

Oxygen Therapy for COPD during Air Travel[42]

Modern aircraft are pressurized to cabin altitudes up to 2,438 m (8,000 ft) although this limit may be breached in emergencies. At 2,438 m (8,000 ft), the PaO_2 will be equivalent to that of breathing 15% oxygen at sea level. In a healthy individual, the PaO_2 at 2,438 m (8,000 ft) will generally fall to 53 to 64 mm Hg. This may exacerbate hypoxemia in patients with COPD, especially those who are hypoxemic at sea level. There are three common methods of assessing the requirement for oxygen therapy during air travel, the so-called preflight hypoxia testing.

i. *Six-minute walk test:* Although not specifically evaluated for the purpose of preflight hypoxia testing, failure to complete the task in terms of distance or time, or moderate-to-severe respiratory distress recorded on a visual analog scale, will alert the physician and the patient to the possible need for in-flight oxygen.

ii. *Prediction equations:* Another method is the use of prediction equations that have been derived from patients with COPD who have had measurements of PaO_2 in a hypobaric chamber, while breathing FiO_2 at 15%. The accuracy can be improved by the inclusion of FEV_1 in the equation. These equations are reliable to establish upper and lower thresholds for "no in-flight oxygen required" (SpO_2 >95%) or "in-flight oxygen needed" (SpO_2 <92%). One commonly used prediction equation is given below: $PaO_2\,(\text{Alt}) = 0.519 \times PaO_2\ \text{ground (mm Hg)} + 11.855 \times FEV_1\ (\text{L}) - 1.760$

iii. *Hypoxia challenge test:* The ideal test is to expose a subject to hypoxia in a hypobaric chamber. The facility for this testing is not widely available. A surrogate is to administer FiO_2 at 15% and measure the PaO_2. Although not validated, a PaO_2 less than 50 mm Hg predicts requirement of in-flight oxygen therapy.

In practice, oxygen is generally prescribed on the basis of the prediction equations as the six-minute walk test is cumbersome and hypoxia testing is not routinely available in developing countries.

PERSPECTIVES OF DOMICILIARY OXYGEN USE IN INDIA

An organized domiciliary oxygen and rehabilitation program is yet to establish at most places in India. In spite of the several limitations, we have used home oxygen therapy in COPD and other chronic lung diseases since 1970s. On an average, 10 to 12 new patients are recruited every year. Chronic obstructive pulmonary disease remains the chief indication for LTOT. Idiopathic pulmonary fibrosis, chronic bronchiectasis, kyphoscoliosis and post pneumonectomy pulmonary hypertension and respiratory insufficiency have been a few other common conditions. Most patients had relied on commercial oxygen supply. In fact some patients from smaller towns had used oxygen tanks procured from vendors using oxygen for welding and other industrial purposes.

In this country, it is important to assess the educational and psychological status of the patient (and the family), social background, place of residence, income and employment position before prescribing the therapy. Availability of an organized supply of O_2 is lacking and the costs are high. Feasibility of supply is poor, much more so in the rural areas and small towns. Occasionally, patients even from smaller towns have succeeded in overcoming difficulties.

Some of the important problems stated by most of the patients related to the difficulties of procurement and costs. There are limited sources of supply. Moreover, the medical expertise and advice to supervise domiciliary treatment is lacking. Patients' resources to afford the treatment are also scanty. There are no clear guidelines available regarding reimbursement of costs on oxygen and the apparatus: A facility available to government and several other private/public sector employees for other treatments. One does expect that most of the difficulties shall resolve in due course of time.

Patient Education in Chronic Obstructive Pulmonary Disease

Tushar Sahasrabudhe

INTRODUCTION

The best possible quality of life to the patient of Chronic Obstructive Pulmonary Disease (COPD) is possible only through better understanding of the patient in the perspective of his/her overall life situation. Active participation of the patient in his/her own care is the key. A free communication between the treating physician and the patient is essential and forms the basis of patient education.

The advantages of the patient education in COPD are many:

- Understanding the disease takes away the fear that arises out of uncertainty.
- The sequence of expected events and the understanding of the impact of treatment on them strongly motivate the patient to adhere to the treatment.
- Understanding of pathophysiology helps the patient to understand the symptoms and the role of interventions.
- Understanding the etiology and exacerbation triggers help in reinforcing the smoking cessation and environmental control strategies.
- Well understood action plan takes away the fear of managing exacerbations and the feeling of helplessness.

The physician should involve the family members in education and motivate the family members in the patient management. This has remarkable impact on overall quality of patient's life and his/her medical care. Once well informed, the COPD patient can become an active partner of the physician. Their contribution in following respects can be extremely valuable.

Patient education is often a neglected area in the overall COPD management, more emphasis is laid on symptom control and prescribing medicines. The education can be gradually imparted, can be easily incorporated in the follow-up schedule of the patients. There is no great need for any extraordinary infrastructure or facilities. The requirements for a good patient education program include:

- An enthusiastic and motivated physician with good communication skills.
- Well motivated patient.
- Charts, posters on lung anatomy, physiology, spirometry, etc.
- Lung models.
- Animated videos that can better explain the disease
- Slide shows on COPD.
- Interviews with other COPD patients.
- Group discussions.

EDUCATION ABOUT THE DISEASE

Disclose and Describe the Disease

It is not unusual for the patient to construe that he suffers from bronchial asthma. As a result, he "considers himself" to be allergic to many food items and inhaled substances, follows many restrictions which are unnecessary. It is essential to explain that despite the similarities, COPD is different than asthma. The disease is the topmost cause of death in Maharashtra, India; but a major section of the society has never heard this term.[1] The physician should avoid using the term "Bronchitis", which is very broad and does not convey the seriousness of the illness.

Discuss the Etiology

Most patients are interested in knowing the cause of their suffering and will actively enquire about it. The first consultation with patient is therefore the right time to begin with smoking cessation, if tobacco smoking is the cause of COPD in that patient. The patient should be made aware that it is a self-inflicted disease and that the tobacco smoking habit is responsible for it.

The best way is to make the patient understand the chronological relation between the smoking and the drop in the lung function.[2]

The lung function usually drops at a steady pace as the age advances. The drop is approximately 25-30 ml per year in a normal healthy person.[3]

There is accumulating evidence to suggest that biomass fuel is largely responsible for the cases of COPD occurring in nonsmokers especially amongst the rural women.[4] It is also important to impart and implement various educational measures to minimize their use and exposure.

Explain the Pathophysiology

Explaining the pathophysiology provides good insight to the patient on his disease. Cough and sputum are very disturbing symptoms for patients with predominant chronic bronchitis. They often wonder where this excess phlegm is generated and urge the doctor to stop it, somehow. They actually change doctors and try many cough suppressants in an attempt to stop the phlegm.

Explanation on the bronchial gland irritation and hypertrophy and assurance that the phlegm can be managed with good clearance techniques eases their discomfort and improves the acceptance of the symptom.

Presence of dyspnea is another disturbing symptom that needs explanation. Attempts at relief with bronchodilators are usually only partial and do not take care of the baseline dyspnea. Exercise is increasingly difficult due to the compromised inspiratory capacity. A thorough explanation of air trapping and bullae formation can improve their understanding. Simple techniques such as "pursed lip breathing" may provide relief from the "balloon" feeling; the significant improvement in dyspnea boosts the confidence of the patient.

The dysfunction of diaphragm due to air trapping can be explained, with the help of figure depicting how a contracted muscle may not be able to perform better mechanical function.

A stretched arm can lift 10 lb of weight easily with the powerful biceps muscle. However, if the elbow is fully flexed, the shortened biceps cannot contract further. The power is therefore greatly reduced and it cannot even hold a tennis ball properly. The diaphragm undergoes the same disadvantage in COPD. The flattened diaphragmatic muscle due to hyperinflation of the lung parenchyma cannot contract further and therefore loses its power, dramatically. It tends to fatigue earlier because of the mechanical disadvantage. Moreover, the work of breathing is exaggerated in COPD, which further tires the diaphragmatic muscle.

The understanding of effect of COPD on pulmonary circulation and consequent right heart failure often alleviates the fear of heart disease and adherence to salt restriction, diuretics and oxygen therapy improves.

Sarcopenia, weight loss and muscle weakness are considered as grievous signs by the patient and he starts losing hope. Explanation of the systemic consequences of COPD including skeletal muscle dysfunction and ischemic heart disease and assurance of the improvement by rehabilitation techniques reduces anxiety and depression to a large extent. It also improves the compliance with the exercise schedule. The knowledge that COPD is a major risk factor for heart diseases may act as a strong motivator for smoking cessation and adherence to the treatment, the heart is usually a more cause of concern then the lungs for a lay man.[5]

Explain the Medical Tests

Tests such as X-ray, spirometry and the six-minute walk test are often advised frequently to the COPD patients. Most patients do not understand the results and are dependent on their doctors for the interpretation. Spirometry values show marginal change or even no improvement over the time. This may be misinterpreted as treatment failure by the patient and this may even lead to treatment default.

The six-minute walk test is valuable as it gives a fair idea of the exercise tolerance of the COPD patient. Recently, it is also been shown to be predictive of disease progression and mortality.[6] Insight into the six-minute walk distance and oxygen desaturation usually helps in the motivation of the patient for the rehabilitation schedule.

EDUCATION TO HELP REDUCE COPD EXACERBATIONS

A patient who has experienced a severe COPD exacerbation recently is at a high risk of another severe exacerbation and death. Even a single exacerbation has a large impact on the patient's life with recovery period stretching over months.[7] The frequency of exacerbations also determines the overall quality of life of COPD patients.[8] Every exacerbation avoided thus has a positive impact, this can be attempted by the means discussed below.

Environmental Control

Most exacerbations in COPD are related to infections and most respiratory infections are transmitted from person-to-person by coughing or spitting. In one study, the responsible pathogen could be identified in 50% of patients hospitalized with non-pneumonic acute COPD exacerbation and 12% were due to viruses.[9] Another study could identify the pathogens in almost 64% of cases.[10] These infections can be avoided by good environmental control although infections related to airway colonization may still occur.

COPD patients should preferably avoid close contact with people suffering from common cold and other respiratory infections. They should use facemasks if necessary. Avoiding crowded places is rewarding. Cleanliness in the surroundings reduces the chances of infection.

Exposure to smoke is also a known trigger for exacerbations. The COPD patients should be instructed to avoid direct smoke exposure such as to domestic smoke, kitchen smoke, mosquito repellants, etc. They should always be motivated to avoid cigarette smoke as well. Long distance road travel in polluted cities can also trigger the COPD exacerbation. Simple measures like shutting the windows, or covering the nose and face are helpful. Environmental pollution due to firecrackers can be harmful for COPD patients, they should remain indoors during such periods.[11]

Vaccination

Since most of the COPD exacerbations are due to infections causes, vaccination plays an important role in reducing the exacerbation rate. It is recommended to give the influenza vaccine annually and the pneumococcal vaccine, once to all COPD patients.[12]

COPD exacerbations are usually due to gram-positive and atypical pathogens, which tend to get colonized in the airways. Attempts to reduce colonization by improving immunity using sublingual or oral freeze dried bacterial lysate of common airway pathogens has been tried. They are able to induce specific antibody response as well as local IgA response. Such preparations are available in market and they have been shown to reduce the exacerbation rate as well as the duration of antibiotic therapy.[13,14]

Regular Medication

Studies have showed that in the cases of severe COPD ($FEV_1 < 50\%$ predicted), use of long-term inhaled corticosteroids reduced the exacerbation rate significantly.[15] It has also been documented in the COPE study that the discontinuation of fluticasone propionate in COPD patients was associated with a rapid onset and higher recurrence risk of exacerbation and significant deterioration in components of health-related quality of life.[16]

This highlights the importance of regular pharmacotherapy. The information on this literature, if shared with the patient, can improve his compliance and reduce the exacerbation rate.

EDUCATION FOR IMPROVING BASELINE LUNG FUNCTION

Bronchodilator Treatment

Unlike asthma, inhalation treatment in COPD does not give dramatic relief from the symptoms. They also do not give apparent "Cure" of the disease. This usually disheartens the patient who is looking for a cure and relief of his symptoms. He then starts questioning the role of inhalers in his treatment and tends to default. The bronchodilator treatment in COPD is usually lifelong and the patient often gets the feeling of getting dependent on it. "Withdrawal" symptoms of discontinuing inhalers strongly demotivates the patient who starts demanding for short courses of treatment with some recovery days in between the courses.

Despite the poor bronchodilator reversibility of FEV_1 in COPD, bronchodilators have appreciable impacts on breathing. Even a marginal improvement in the radius of the airway leads to a much larger reduction in the airway resistance. The explanation of these facts encourages the patient to take his treatment regularly.

Large one-year trials have found the combination of LAMA and LABA to significantly improve health status as assessed by Saint George's Respiratory Questionnaire (SGRQ).[17]

The patient needs to be fully aware of the dosages, effects and side effects of all his long-term medication. Possible effects on glaucoma, urine retention need to be informed as the old man often has prostate enlargement. Regular use of tiotropium has been shown to improve inspiratory capacity and reduce dyspnea leading to 41% increase in cycle endurance in a study.[18] Presences of ischemic heart disease, hypertension or use of beta-blockers, all need consideration in formulating the treatment strategy.

Alternate Therapy

Many patients of COPD, fed up of long-term medicines, are still looking for cure. They are likely to try alternate therapies, such as ayurveda, homeopathy, yoga or naturotherapy.

Alternate medicines should be tried with caution without defaulting the current pharmacotherapy. Yoga needs a special mention. With recent popularity of yoga, many COPD patients may attempt doing "Pranayama" for improving their lung capacity. Deep-breathing exercises may actually be helpful for these patients. However, they should avoid forced expiratory exercises. This may increase the risk of pneumothorax in patients with emphysema and bullae.

Sputum and Cough Management

The sputum in COPD patients is often sticky and difficult to expectorate. Vigorous bouts of coughing may exhaust them quickly. A simple advice on steam inhalation eases their expectoration. Oral mucolytic can be prescribed intermittently. COPD patients should always be discouraged to use cough suppressants. Stagnated mucus may actually increase the chance of an infective exacerbation. Sufficient intake of water is very important.

Oxygen Therapy

Most patients with very severe COPD do develop significant hypoxia. Domiciliary oxygen therapy has been shown to improve survival, also reduces the morbidity and delays diaphragm fatigue.[19] It is important to explain that oxygen therapy is meant only to supplement the body's need for oxygen which the lungs and ventilatory system are not able to fully satisfy. The therapy has no impact on the disease as such. However, the body organs starved of oxygen, function better and for longer period with oxygen supplementation. This improves both the quantity and quality of life.

Correct Use of Inhalational Devices

The success of inhaled therapy largely depends on the correct technique of using the device. Today, a large range of inhalational devices are available. Selection of the device that suits the patient the most and demonstration of correct inhalation technique are of primary importance. In addition to the erroneous technique of inhalation, the elderly COPD patients have additional problems. Diminished eye sight, poor hand-mouth coordination, and senile tremors, all can reduce the efficacy of inhaled treatment. These issues need to be addressed carefully by the treating physician.

Treatment of Pulmonary Hypertension (PH) and Cor Pulmonale

Severe COPD patients eventually develop significant pulmonary hypertension, followed later by congestive heart failure. Reduction in pulmonary arterial pressures have shown to improve the exercise capacity of patients. Oxygen therapy is an important supplement for successful reduction of PH.

PULMONARY REHABILITATION (SEE CHAPTER 89)

It is an art of medical practice wherein an individually tailored, multidisciplinary program is formulated, which through accurate diagnosis, therapy, emotional support and education; stabilizes or reverses both the physiology and psychopathology of pulmonary diseases and attempts to return the patient to the highest possible functional capacity allowed by his pulmonary handicap and overall life situation.[20]

Simple exercises form the basis of rehabilitation programs, and patients need good training on them preferably by a trained physiotherapist. Pulmonary rehabilitation can reasonably improve the physiological and psychological status of the COPD patients.[21]

Lower Limb Muscle Training

Simple walking, climbing or more sophisticated exercise, such as the treadmill significantly, improves the muscle power, reverses the deconditioning, increases aerobic enzymes in skeletal muscles and reduces lactate levels. Exercise also has a strong antidepressant effect. It motivates the patient and reduces the fear of dyspnea.

Upper Limb Training

Arm elevation, arm cranking and weight lifting can improve vital capacity, oxygen uptake and arm function.

Ventilatory Muscle Training

Diaphragm, the main muscle of inspiration is fatigued in sever COPD patients. Techniques such as abdominal breathing, incentive spirometry and breathing through devices with resistance valves improve diaphragm strength and delay fatigue.[22]

Pursed Lip Breathing

The main mechanism behind air trapping is the closure of bronchi at the equal pressure point where the intraluminal and intrathoracic pressure matches. Voluntary increase in intraluminal pressure can keep the airway patent and help in the release of trapped air. This can be achieved by ballooning the cheeks and slowly exhaling the air. This maneuver called as “Pursed Lip Breathing” is effective, many patients learn it on their own.

EDUCATION AND DISCUSSION ON DAILY LIFE ISSUES

A patient with very severe COPD feels significantly handicapped while performing day-to-day chores. Inability to perform simple activities such as changing the clothes or taking bath can be really demoralizing for the patient. Patients with moderate-to-severe COPD however suffer from more subtle frustrations. These need to be carefully probed and resolved.

Recreation

A man who has spent years of active life gets gradually bed ridden as his COPD progresses, he starts needing help for even simple daily routine. “Take plenty of rest” is an advice easier given than followed. Lying on the bed for most of the time can be really frustrating. Careful assessment of the functional capacity of the individual followed by planning of recreational activities within his reach acts as a good motive for active living.

Sexual Dysfunction

Patients of COPD commonly have sexual dysfunction. Erectile dysfunction is observed in 75.5% of patients of COPD as per the International Index of Erectiole Dysfunction (IIEF), it was proportionately more common in advanced COPD.[23] Failure to perform a sexual act can be a hidden cause of frustration and depression, which the patient may never discuss with his doctor.

Diet

It is common for the COPD patients to follow plenty of dietary restrictions, such as the avoidance of lemon, ice creams, curds, pickles, juices, bananas, etc. Except for the patients with predictable triggering of exacerbation with a particular food item, no specific dietary restrictions are necessary. Patients with hypoventilation should however be more careful about their diet. A high calorie and low carbohydrate diet is recommended. Carbohydrates are more completely metabolized and the end product is carbon dioxide. Patients with existing hypoxia and hypercapnia may then end up consuming more oxygen and producing more carbon dioxide which their lungs and ventilatory system cannot handle.

Sleep Apnea

Daytime sleepiness, morning headaches and hypertension should alert the physician to the possibility of sleep apnea. Unfortunately, daytime sleepiness is frequently attributed to old age, boredom and general weakness, and patient may not even complain about it to the doctor. Hypertension, common in an aged smoker, is also similarly not attributed to the possibility of sleep apnea. COPD patients may desaturate significantly in sleep. Vascular changes can occur very fast leading to rapid rise in pulmonary arterial pressures. The possibility of sleep apnea therefore, needs to be looked into.

DISCUSSION ON SPECIAL ISSUES

Travel

In the modern times, air travel has become common, and it is estimated that about 5% of the patient’s traveling by air may be suffering from chronic respiratory diseases such as COPD. Most commercial aircrafts are pressurized to 8000 ft altitude where the air/oxygen pressure drops to 15%. This may be detrimental for a patient whose baseline oxygen saturation is below 92%. These patients need to make arrangements with the airlines for in-flight oxygen. The cabin air is usually dry. Prolonged air travels with dry oxygen, sitting position and high altitude, all can precipitate respiratory and/or congestive cardiac failure in a COPD patient. Careful pre-flight assessment with oxygen saturation monitoring and hypoxia test is therefore recommended[24] (See Chapter 104).

Patients on domiciliary oxygen planning to travel by train need to arrange for portable oxygen cylinders. Prior permission from railway authorities is necessary.

Fear of Exacerbation

Patients who have experienced a severe exacerbation, especially the one requiring hospitalization or mechanical ventilation, are under constant fear of another exacerbation. The physical and financial dependence on other family members aggravates the fear. Although it is important to detect and treat an exacerbation early, it may be impossible for the COPD patient to see the doctor in time.

Having a handy self action plan is very useful and the treating physician should provide this information. Forming the support groups of COPD patients staying in nearby areas and conducting their quarterly meetings are useful. A list of available medical resources and the community services with the phone numbers is handy. Sharing of experiences, knowledge, treatment options as well as emotional support, all help in alleviating the fear of an exacerbation.

Depression

It is estimated that 20 to 60% of the COPD patients are depressed. The reasons are many fold. Poor effort tolerance makes travel difficult. Disturbing cough and dyspnea lead to social withdrawal. Anxiety about illness, fear of exacerbation adds to the stress levels of the patient. Guilt, either self-imposed or by constant criticism by the family members makes the situation worse. Actually, a patient with severe COPD needs help rather than criticism for his past habit of smoking; in this case the counseling of family members is helpful. Sleep disturbances, sexual dysfunction and disability make life less enjoyable. A strong feeling of dependency on the family members hurts the ego badly, especially for a person who was the family head in a dictating position for years. Indoor treatment of exacerbation especially if needing mechanical ventilation is very costly. Daily pharmacotherapy and oxygen therapy are also not cheap. These financial issues add to the depression.

Psychological interventions, cognitive behavioral interventions and counseling helps alot.[25] Rapport with treating doctor and his moral support are vital. Family members can help in daily activities, supervision of medical treatment, and purposeful involvement in family/social gatherings.

Surgery

An old patient of COPD requiring surgical intervention for some unrelated problem such as acute abdomen or for fixation of a fracture is a challenge. Optimization of medical treatment, good bronchial hygiene techniques and good preoperative preparation are necessary and helpful to reduce the complications.[26] These patients are at particular risk of some postoperative complications, such as mucus plugging, pneumonia, COPD exacerbation and pulmonary embolism.

Frequent discussions with family members on need for surgery are essential. Generally, early ambulation helps. A COPD patient getting bed ridden for a longer time is likely to develop complications.

PREVENTION OF COPD

COPD has been redefined as "a treatable and preventable disease". Early detection and early intervention have been shown to increase the lifespan as also the quality of life. The prevention or halting progression of COPD would then revolve around: Smoking cessation, reducing biomass fuel exposure and early detection of COPD. Smoking cessation and prevention is the most important issue. Information on the subject is widely available on the Internet as well as in published literature, including from India.[27] Other measures of protection from air pollution are also important.

Alternate means of cooking, such as using natural gas, biogas or improvised stoves for cooking, can reduce this risk to a large extent.

Vehicular air pollution is also shown to increase the risk of developing COPD and efforts to tackle the same are necessary. People with occupations such as auto-rickshaw drivers or traffic policemen should use necessary personal protective equipments such as face-mask.

EARLY DETECTION OF COPD

The National Lung Health Education Program (NLHEP) recommended spirometry testing for all smokers above the age of 45 years and for anyone with chronic cough, mucus hypersecretion or wheeze.[28]

End-of-life Communication and Palliative Care in Advanced COPD

Sujeet Rajan

INTRODUCTION

This is by far the most challenging part of managing advanced Chronic Obstructive Pulmonary Disease (COPD) for respiratory physicians. Physicians managing COPD must be both confident and competent in caring for their patients in the final phase of their illness. Both the patient and his family must be assisted to face inevitable death. It is not surprising that in a study of 100 patients with COPD, 58% preferred a plan of comfort care over a plan to extend life and 78% did not want ventilation in intensive care.[1] Decisions to limit support in terminal illness have become routine in Europe and the United States. In India, however, these decisions are far more difficult due to the lack of palliative care orientation, unawareness of ethical issues, culture of "fighting till the end" and legal and administrative prejudices.[2] (See also Chapter 168 on End-of-life Care)

ADVANCED TERMINAL COPD

Advanced terminal COPD comes under the spectrum of "end-stage lung disease" which basically implies that the patient now has very severe airflow obstruction, often with a Forced Expiratory Volume in One Second (FEV_1) of 0.5 liter. There is chronic hypoxemia with or without hypercapnia. The terminal phase of COPD is difficult to define, it can vary from one patient to another based on the actual lung function, presence of pulmonary hypertension, personality and attitude towards illness, and of course, the social status of the patient. At one spectrum, one could get a patient with an FEV_1 of 45% of predicted, from a lower socioeconomic strata who has almost permanently confined himself to his home, to another from a higher socioeconomic strata with an FEV_1 of 34% who is raring to play golf.

A good way to define terminal disease is when survival is expected to be less than two years. This allows the primary care physician with help from the specialist to guide the patient and the family on how the future is likely to evolve. Though two years sound a realistic end-point before which to start communicating, it isn't so easy in COPD, which reflects certain death at an uncertain time. Many, in fact most patients with COPD, do not die of progressive respiratory failure, but of cardiac disease or cancers. This was clearly evident from the review of the mortality data from the Towards a Revolution in COPD Health (TORCH) Study.[3] Therefore, a reasonably healthy COPD patient may actually and very often die suddenly of myocardial infarction. This may not be easily predictable. However, that needs to be a factored point when discussing end-of-life issues with the patient.

PROGNOSIS OF ADVANCED COPD

Equally important is to realize the prognosis of patients with COPD. Table 87.1 lists a good guide in deciding when to bring up the topic for discussion with patients discharged after an Acute Exacerbation of Chronic Bronchitis (AECB).

TABLE 87.1: Post-discharge mortality in two studies

Ai Ping et al[4]	*Breen et al*[5]
• 6 Months: 39%	6 Months: 41%
• 1 Year: 43%	1 Year: 49%
• 3 Years: 61%	2 Years: 58%
• 5 Years: 76%	3 Years: 64%

A Canadian study suggested that after six months of discharge from a hospital following AECB, only 25% of patients were well and with a good quality of life; 44% of them had been re-admitted by then.[6] This illustrates how important it is to bring up this issue at the stage of hospital discharge from an AECB. The author will discuss other situations to define advanced terminal COPD, but equally important is the presence of pulmonary hypertension and right ventricle (RV) dysfunction, the presence of which itself, is indicative of a four-year mortality of 73%.[7] The timing of death, however, remains almost impossible to predict. As mentioned in the example earlier of myocardial infarction as a cause of death, the timing of death is poorly estimated even within a week of death.[6]

Issues Involved in Treating Advanced Terminal COPD

When the disease gets worse, and as the pharmacological options become limited, the care gets harder and more challenging. Some of the questions to handle at this stage are as follows:

- Handling the fear of a dying patient. The fear of suffocation or choking to death is real; watching someone going through this stage can be equally devastating for the family.
- When the next exacerbation occurs, should the patient be *actively* treated to prolong life, or treated so as to allow smooth transition from life to death?
- How *much* active treatment is appropriate? Should the next exacerbation be treated at home (esp. in a financially drained patient) or at a Hospital?
- If treated at home, should noninvasive ventilation be used (machines can now be rented or bought by patients)?
- If treated in the hospital, should the patient be treated in the room/ward or intensive care unit (distanced from relatives and loved ones)?
- If a decision has been taken that patient is not to be transferred to intensive care unit (ICU), what is the maximum time for the patient to remain in the ward/room setting?
- If a decision to transfer to ICU is taken, is the patient agreeable to be *invasively* ventilated?
- If *no* to the above question, what will be the maximum care offered to the patient in the ICU, which cannot be given in a room/ward?
- If the patient has said no to any of the above "active treatment" options, has an "advance directive" been obtained from the patient?
- Are the relatives taking most of the decisions for the patient (common in Indian scenario, where shielding the patient from an adverse diagnosis or prognosis is common)? Is the patient educated enough to take a better decision himself? If so, is the "relatives" opinion/decision final?
- If the patient is unconscious (with no advance directives), how does the discussion with family ensue?

GOOD DEATH IN COPD: IMPLICATIONS

An excellent study identified five issues that a patient may wish to see addressed before he dies.[8] As a physician it is important to be very sensitive to these issues:

- Adequate relief of symptoms, especially pain and dyspnea
- No inappropriate prolongation of life
- Sense of control of their own person
- Relief of the burden to their family
- Strengthening of family relationships

Patients with COPD are not always able to die quietly, peacefully, or in their own homes. The patient and the families' descriptions of breathlessness challenge the definitions of a 'good death'. Patients often die in the ICU or hospital, and it could be argued that dying in an environment away from the home setting has meant that we have lost our ability to communicate with the dying patient.[9]

For the COPD patient this is a constant dilemma. By suffering at home all the time, he has already experienced a "social" death for years. He is often "dying and living" at the same time. At the end, when brought to a hospital, he is additionally subjected to the regular procedures of a "hospital management," which could range from simple intravenous lines to endotracheal intubation and invasive ventilation. Having undergone a prolonged period of reduced physical and social functioning, they are actually hardly "living" in the true sense much before they die. The COPD patient, therefore, challenges the concept of a "good death." This remains one of the most difficult situations in dealing with patients with any kind of advanced lung disease.[10]

Appropriate Time to Begin Discussions on End-of-life Issues with COPD Patients

As mentioned earlier, when survival is expected to be below two years, the time has come to start a discussion with the patient. Studies have shown that patients appreciate physicians who discuss these issues with them, in contrast to many physicians believing that patients may not be ready for the same.[11] Patients appreciated physicians who are honest and straightforward, are willing to talk about dying, are good at listening, give bad news in a sensitive way and most importantly, are sensitive to the timing of such discussions. By avoiding the topic, patients are less satisfied. Introduction of the topic actually allows patients to engage in a good discussion and maintain a sense of hope with less depression, even when the prognosis is poor.

Patients perceive their physicians based on ***what*** (the content) they communicate and ***how*** (the process) they do it largely. Unfortunately, most of these discussions take place outside the ICU, and often when the patient himself is unable to take a decision on his own. This delay in communication must be avoided and every attempt should be made at the out-patient level to start such discussions where appropriate, and of course after a full review of diagnostic tests and ongoing treatments. Sometimes, even a second opinion helps before deciding that the patient and the family needs such a discussion. End-of-life discussions in COPD can be started in the presence of different disease criteria (Table 87.2).

TABLE 87.2: Different criteria in COPD when end-of-life discussion can happen

- $FEV_1 < 30$ % (during the stable period)
- Oxygen dependence
- One or more hospitalizations in the past one year with AECB
- Left heart failure
- Weight loss/cachexia and increasing dependence on others
- Age more than 70 years

PRINCIPLES OF END-OF-LIFE COMMUNICATION IN COPD

1. **Ethical Principles:** The basic ethical principles consist of Beneficence; Nonmaleficence; Autonomy and Justice, i.e. fairness in the physician's approach. Physician should not provide investigation or treatment that will harm or serve no purpose. Avoid imposing futile treatments on the patient. Treatment aimed at a specific symptom may have adverse effects that may shorten life, e.g. morphine. When the benefits of alleviating the patient's suffering outweigh the risks, then such therapy is acceptable, and is not considered euthanasia.
2. **Cultural Principles:** Surprisingly, there is very little information on how the influence of culture affects the patient and family. Culture encompasses the patient's beliefs, life's experiences, values, attitudes and assumptions. This is not necessarily related to the ethnicity of the patient. Culture can affect the entire way in which a patient approaches his life, disease and death. This culture needs to be respected by the physician. Eye contact with the patient, physical touch and privacy often varies between cultures. The entire communication process of "breaking bad news" can vary between cultures, and understandably, this can have profound effects on management planning. Respect given to the patient's cultural preferences has a tremendous positive impact on the patient and the family. Trust is immensely improved and strengthened when this aspect of the patient's whole is also respected.
3. **Incompetent Patient:** Depression can often affect the decision-making process of COPD patients. This must be carefully looked for before labeling the patient as poorly responsive to suggestions *or* incompetent in making a decision. For the actual incompetent patient, one has to often ask the family for end-of-life directives. Ideally, this should be the spouse or children. It is important here to understand if the patient had ever expressed any desires about the way he should be managed towards the end of his life. Often, the patient has expressed such views to the family, such as not being ventilated or brought to ICU at all. Our culture often shields the patient from bad news, despite the patient realizing, long before the family, that he is headed in a downward trajectory.

Sadly, even in competent patients, the family often incorrectly states a patient's wishes.[12] When life and death decisions are at play, the family must be told that the decision is not their responsibility, but that they are simply guiding the physicians in their decisions.

Place Where End-of-life Communication Should be Done

Communication is most often done outside an ICU cubicle! This should be avoided as far as possible. A large quiet room with privacy and confidentiality is the best. Emotional outbursts are not uncommon by family members. In some cultures, the patient is asked as to whom he would like to have present in the room. In others, the patient is often left out of the discussion, leaving this to responsible family members whom he entrusts with all decisions pertaining to his life and death. It is important to counsel these members extensively.

When such discussions occur, ensure that everyone's opinion in the room is heard out and try to end it on a final collective decision that everyone is agreeable to.

How and What Needs to be Done[13]

- After listening well to the patient and the family, you will be able to understand their expectations and come to a consensus on what needs to be done. The levels at which things for advanced COPD can be planned are outlined below:
  - Level 4: All conditions investigated and treated, including Cardiopulmonary Resuscitation (CPR)
  - Level 3: Above, except CPR (the patient can still be intubated and ventilated)
  - Level 2: Potentially reversible conditions are investigated and treated (can be done at home or hospital)
  - Level 1: Main focus is on palliative care—symptom relief is the focus of all treatment. (intravenous feeds and RT feeds are avoided)
- As mentioned earlier, when planning the foreseeable level of care, always use words like "if" rather than "when." "When" seems to be a prediction of doom, but "if" is more often seen as uncertainty and allows patients to balance hope and acceptance.
- Discuss the implications and consequences of treatments, in the light of the disease prognosis. It is imperative that patients' and their families' understand the "misery of doing everything." Often patients with unlimited financial resources believe that "everything" must be done for a dying patient. "Everything" includes more drugs with adverse effects; mechanical ventilation; more procedures on an ill patient; and not to forget the ongoing mental stress to the patient and the family members, many of whom have not been actively involved in this decision to do "everything."
- Don't Forget About Depression and COPD: Depression often affects decision-making by the COPD patient and this should not preclude the introduction of an intervention when it can actually help to improve the patient's quality of life.
- Manage symptoms as possible in the following ways:
  - *Dyspnea:* Over 50 % patients suffer from dyspnea, 90% by the end of their life. Dyspnea is often aggravated by anxiety, low-dose anxiolytics like alprazolam can often help, especially if back-up noninvasive ventilation is available. Pharmacologic therapy is often limited after nebulized bronchodilators and systemic steroid have been used. Though oxygen and noninvasive ventilation help, morphine may need to be used when dyspnea worsens. The benefits are largely related to reduced ventilation and the sensation of dyspnea. Unlike pain management, the long-term effects are not so beneficial and side effects are common. Relaxation breathing, upright posture and sometimes music therapy can also help in palliative care. Slow-paced music is usually preferred over fast pace. Music therapy is shown to be superior to progressive muscle relaxation in acute exacerbations.[14]
  - *Cough:* Often, suppressive therapy works for cough. Sometimes systemic steroids are needed. Inhaled local anesthetics can help at times. Physiotherapy may help to control secretions, but adequate hydration goes a long way in ensuring that thick secretions do not impair the ability of the patient to protect his airway.
  - *Insomnia:* Not uncommon in advanced COPD, usually due to orthopnea. Anxiety, depression and theophylline can also contribute. Oxygen to relieve nocturnal desaturation often helps. Non-benzodiazepine sedatives like zolpidem and amitriptyline may help. Benzodiazepines should be avoided as far as possible.
  - *Fatigue:* Lack of exercise, low body mass index and insomnia all contribute to fatigue. Never miss out treatable causes like anemia (iron or B_{12} deficiency) or thyroid disease. Sleep disturbance is often a cause of fatigue and must be addressed.
  - *Delirium:* Confusion occurs in a large number of patients as they approach death. Medications, especially opioids and metabolic disturbances can contribute. After correction of hypoxia and hyponatremia, haloperidol can be tried as a good first-line choice for this symptom. As the need for haloperidol increases, more aggressive sedation may be required and the family should be informed about this requirement.
  - *Cachexia and weight loss:* A poor prognostic sign, this catabolic state often is a result of increased minute ventilation. Mouth breathing and aerophagy aggravate anorexia. High calorie supplements can help. Sometimes, prokinetics help by improving gastric emptying. Foods liked by patient should be provided, including alcohol. Though weight loss can be explained to families as a body's way of shutting down, it is often followed by desperate attempts to feed (and often overfeed) the patient. This must be avoided as metabolism will increase further, putting further load on the respiratory system.

- Judicious use of Noninvasive Ventilation: Noninvasive ventilation has significantly helped many COPD patients die a more comfortable death. Just the ability to speak and eat a bit too makes noninvasive ventilation so much less intrusive than an endotracheal tube or a tracheostomy. Noninvasive ventilation at home has also reduced the number of terminally ill COPD patients reaching the hospital for the inevitable. Though the machines are expensive to purchase, rentals on a daily or monthly basis are now available in several cities.

CONCLUSION

To conclude, end-of-life communication and palliative care is cardinal in the overall management of severe, advanced COPD. As the disease gets more and more severe, less and less specific therapies are likely to benefit the patient and more supportive and palliative care becomes the order of the day. It is imperative that not just respiratory physicians, but primary care physicians too, better understand the process of dying in these patients. It will help them deal with death much better.

Smoking / Tobacco Control

Virendra Singh, Bharat Bhushan Sharma

INTRODUCTION

Tobacco smoking is one of the most important factors in the occurrence and progression of chronic respiratory illnesses. It is also considered the most preventable factor leading to morbidity and mortality.[1] Tobacco cessation confers health benefits, which are evident in former smokers who have lower relative risk of death in all disease categories.[2] Quitting smoking slows down the accelerated rate of lung function decline that occurs in susceptible smokers.[3] Despite the knowledge of beneficial effects of cessation of tobacco, a large number of users fail to stop smoking. Although, 70% of the smokers think of quitting and approximately 40% try to quit each year, hardly 5% remain abstinent.[4] In addition, tobacco contributes to the generation of revenue and employment for people of many developing countries. Tobacco product manufacturing companies have exploited all these factors nicely to their advantage.

Recent scientific advancements have led to the development of effective treatment modalities for tobacco addiction. However, overall emphasis on smoking cessation activities is poor, at the same time there is a growing number of new smokers, especially in developing countries. Thus, tobacco smoking continues to remain a big public health problem. The present chapter is divided into two parts. First part gives a brief description of magnitude of problem related to tobacco use and smoking. The second part deals with evidence based recommendations for smoking control methods.

TOBACCO SMOKING

Historical Aspects

Tobacco cultivation was started around 8,000 years back in the American continent. Nevertheless, it was introduced to the rest of the world only about 500 years back. In later part of 15th century, Christopher Columbus while discovering America, found that native people cultivated and used tobacco.[5] Columbus brought tobacco to his country, Spain.[6] Within a few decades, tobacco use spread to the rest of the world from Europe. Portuguese merchants brought tobacco to India. Harmful effects of tobacco use were identified quite early and many European countries started imposing bans on smoking in the 17th century.[7]

However, smoking bans were lifted subsequently because medicinal properties of tobacco were highlighted and tobacco trade became an important source of income for governments. Around middle of the 20th century, tobacco use was linked to development of lung cancer.[8] Subsequently, it was linked to many other diseases. Environmental tobacco smoke exposure (passive or secondhand smoking) was also linked to a variety of health problems. Despite of all these, tobacco use continued to increase, especially in the developing countries.

Epidemiology

Prevalence of Use

India is the second largest producer and consumer of tobacco products worldwide.[5] According to a national survey on adults in India, 47% of males and 14% of females are current tobacco users. Among male tobacco users, 30% are smokers while the rest use chewing tobacco.[9] Though in adults, tobacco use among males is 10 to 15 times higher in comparison to females, in adolescents this gap is reducing fast. Global Youth Tobacco Survey (GYTS) has shown that in 8th to 10th grade school-going adolescents, in 13–15 years age group, male users were only about one and a half times the female counterparts.[10]

In developed countries tobacco use is showing a decreasing trend. Among adults in USA, 27% males and 19% of females are current tobacco users. More than 75% of them are smokers and the rest use smokeless tobacco.[4]

Type of Smoking

Cigarettes are the most common mode of tobacco use globally. Smoking pattern in India shows that around 70% to 80% of people use *bidis*, 15% to 25% cigarettes and about 4% smoke *hookah*.[11]

Mortality Attributed to Tobacco Use

Almost half of people who use tobacco are killed by tobacco-related diseases. World Health Organization (WHO) estimated that 100 million deaths were caused by tobacco in the 20th century. If current trends remain unaltered, there will be up to one billion deaths due to tobacco use in the 21st century. There are around one billion smokers in the world today and 500 million are expected to die due to tobacco-induced diseases. Approximately, one million people are killed by tobacco-related diseases each year in India, where 10% of the world's smokers live.[12] Tobacco-related diseases are important cause of death among middle-aged men in India; almost 25% deaths in this group are due to tobacco-related diseases.[13]

Factors Responsible for Smoking

It is still quite intriguing why some people are able to quit smoking quickly and easily while others smoke right up to their untimely death. Apart from strong addiction power of tobacco, the answer to this question lies in variable nature of tobacco smoking behavior. Tobacco habit may be considered as a complex chronic disease just like diabetes or Chronic Obstructive Pulmonary Disease (COPD). Early life exposures, environmental factors like living in an area that restricts smoking and genetic factors play important role in the continuation of smoking (Fig. 88.1).[14] A study among school children in Rajasthan showed that children were more likely to smoke when they were exposed to smoking advertisement or to other smokers in the family.[15] Therefore, strategies to persuade a person to stop smoking must address all of these issues.

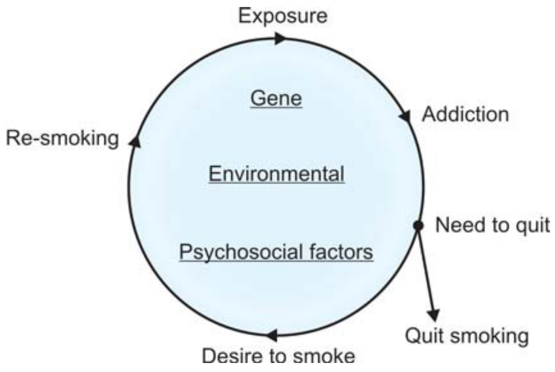

Fig. 88.1: Origin and perpetuation of addiction[5,14]

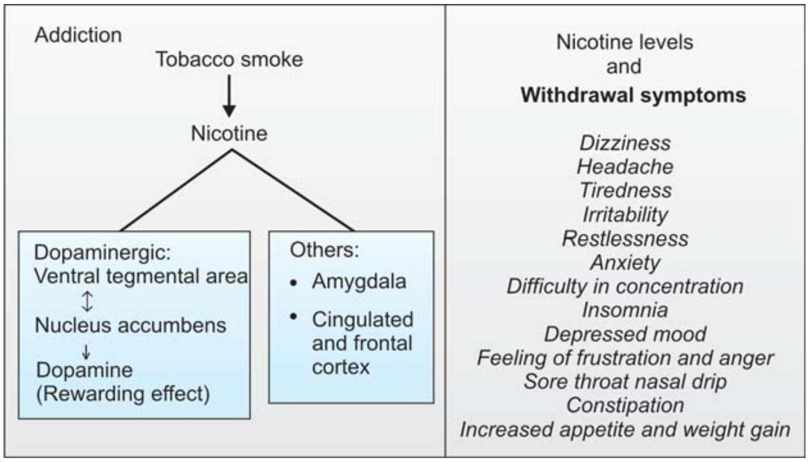
Neuronal Pathophysiology

Various neural pathways and transmitter systems have emerged to explain the psychoactive and addictive properties of nicotine. Nicotinic acetylcholine neurons located in the ventral tegmental area show increased activity with nicotine administration. They concomitantly trigger the increased release of dopamine into the nucleus accumbens (Fig. 88.2). Addiction to nicotine is believed to result from increased release of dopamine in the region of nucleus accumbens.[16,17] Recent evidence suggests that excitatory amino acid systems, in particular, *N*-methyl-*D*-aspartate (NMDA) receptors are implicated in the behavioral changes that occur following long-term nicotine use, including tolerance, sensitization and physical dependence.[18]

Withdrawal Symptoms

Similar to addiction with other drugs, nicotine withdrawal leads to a number of clinical manifestations (Fig. 88.2). Nicotine withdrawal symptoms are time-dependent, at times lasting for many weeks. These include symptoms like irritability, anxiety, depression, difficulty in concentrating, weight gain, restlessness and many more.[19,20] The level of nicotine dependence is the most important factor that determines the intensity of withdrawal symptoms. We can assess the level of nicotine dependence by objective measures such as Fagerström's test for nicotine dependence, which measures addiction on a 0–10 scale. The two most important parameters of the test are the length of time after waking before the first cigarette is taken by



Addiction
Tobacco smoke
Nicotine
Dopaminergic:
Ventral tegmental area
Nucleus accumbens
Dopamine
(Rewarding effect)
Others:
Amygdala
Cingulated and frontal cortex
Nicotine levels and Withdrawal symptoms
Dizziness
Headache

individual and the number of cigarettes smoked per day.[21]

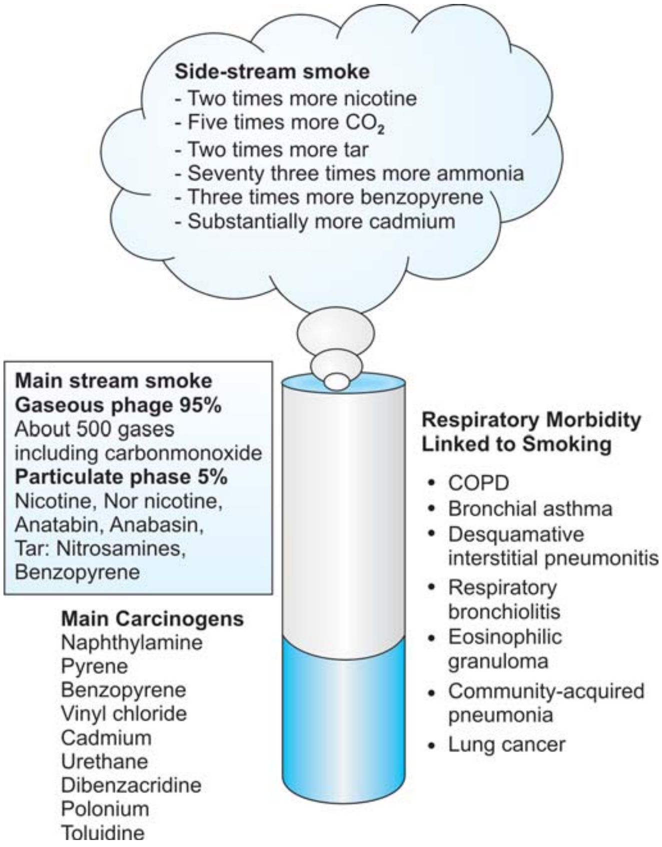
Harmful Effects of Smoking

Toxins of Smoke

Cigarette smokes contain a significant concentration of oxidants, which are responsible for damage and causation of respiratory and other illnesses. Approximately, 4,000 chemicals have been identified in tobacco smoke of which at least 250 are known to be harmful (Fig. 88.3). These substances generated by smoking stimulate inflammation in the lung and its airways.[22] Cigarette smoking leads to inflammatory changes in the central and peripheral airways as well as the lung parenchyma. These changes finally lead to structural remodeling because of repeated injury and repair.[23] Respiratory morbidity due to tobacco smoking is varied and vast in nature, includes obstructive as well as restrictive lung diseases and lung cancer.[24]

Type of Smoking and Harm

Bidis produce three times more carbon monoxide and nicotine and five times more tar than regular cigarettes.[25] *Bidi* smokers have a three-fold higher risk of oral cancer compared with nonsmokers and are also at increased risk of lung cancer. *Hookahs*, a popular form of smoking in rural areas of India, are also linked to lung disease and cancer.[26]



Side-stream smoke
- Two times more nicotine
- Five times more CO_2
- Two times more tar
- Seventy three times more ammonia
- Three times more benzopyrene
- Substantially more cadmium
Main stream smoke
Gaseous phage 95%
About 500 gases including carbonmonoxide
Particulate phase 5%
Nicotine, Nor nicotine, Anatabin, Anabasin,
Tar: Nitrosamines, Benzopyrene
Main Carcinogens
Naphthylamine
Pyrene
Benzopyrene
Vinyl chloride
Cadmium
Urethane
Dibenzacridine
Polonium
Toluidine
Respiratory Morbidity Linked to Smoking
COPD
Bronchial asthma
Desquamative interstitial pneumonitis
Respiratory bronchiolitis
Eosinophilic granuloma
Community-acquired pneumonia
Lung cancer

Fig. 88.3: Tobacco toxins and respiratory ailments[24,26]

Sidestream or Secondhand Smoke

Smoke emitted from the burning end of a cigarette or *bidi* while not being smoked, is called sidestream tobacco smoke. Both the mainstream and the sidestream smoke contain similar components, but the sidestream smoke is three to four times more toxic per gram of particulate matter than the mainstream tobacco smoke (Fig. 88.3).[27] Toxic chemicals from secondhand tobacco smoke stick to rugs, curtains, clothes, food or furniture and can remain in a room even for weeks and months after someone has smoked there.[28] Tobacco toxins that build up over time, coat the surfaces of room and materials are sometimes referred to as thirdhand smoke, approximately 50 of which are known to cause cancer.[29]

Passive smoking during childhood is considered as a risk factor for the development of asthma. Uncontrolled asthma is associated with parental smoking. Furthermore, asthmatic symptoms decline sharply after the Environmental Tobacco Smoke (ETS) exposure is controlled.[30]

Tobacco-Related Diseases

Smoking causes cancers of many organs. Cancer of lungs, tracheobronchial tree, mouth, esophagus, stomach and urinary bladder are mainly linked to tobacco use. Tobacco use is associated with higher rates of coronary artery disease, stroke and atherosclerosis.[31] Respiratory diseases caused by smoking include COPD, tuberculosis and lower respiratory tract infection[31] (Fig. 88.4). Globally, COPD is the most common cause of death among smokers. Likewise, smoking is responsible for half of all male deaths from tuberculosis in India.[13]

Loss of Revenue due to Tobacco

In India, the cost of treating tobacco-related disease is more than double than the revenue the government gets from the tobacco industry.[32] Besides this, there is an uncountable fiscal and personal loss to the families and society due to early deaths of the smokers.[33]

Benefits of Smoking Cessation

Smoking cessation has definite personal and health benefits that may be divided into short- and long-term benefits (Table 88.1)[20,34]

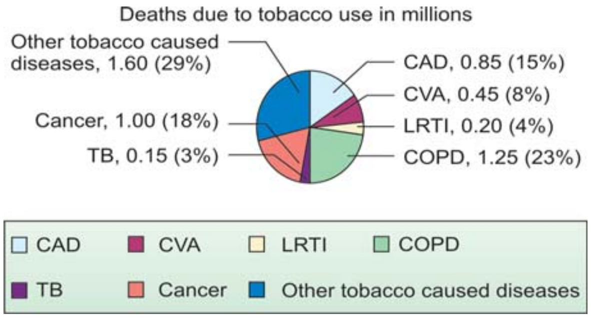


Fig. 88.4: Leading causes of mortality due to tobacco: Globally[31]

TABLE 88.1: Beneficial effects of smoking cessation [20,34]

Immediate rewards of quitting	*Respiratory benefits over time*
These rewards can improve day-to-day life to a great extent: • The breath smells better • Stained teeth get whiter • Bad smelling clothes and hair disappear • Yellow fingers and fingernails disappear • The food tastes better • The sense of smell returns to normal • Breathlessness on everyday activities is reduced	**8 hours after quitting:** Oxygen levels in the blood return to normal. **12 hours after quitting:** The carbon monoxide level in blood drops to normal. **48 hours after quitting:** Nicotine is no longer detectable in body. The ability to taste and smell improves. **72 hours after quitting:** Breathing becomes easier as the bronchi. relax. Energy levels increase **2 weeks to 3 months after quitting:** Circulation improves and lung function increases. **1 to 9 months after quitting:** Coughing and shortness of breath decrease; cilia regain normal function in the lungs, reduce the risk of infection. **10 years after quitting:** The lung cancer death rate is about half that of a person who continues smoking. Risk of cancer of the mouth/ throat also decreases.

Short-Term Benefits

Immediate benefits of smoking cessation include a decline in carbon monoxide levels in the blood, return of pulse rate and blood pressure to normal levels. Personal benefits include improvements in breath smells, stained teeth, bad smelling clothes or hair, colored fingers and fingernails, taste of food, sense of smell and breathlessness on everyday activities.

Long-Term Effects

In persons who quit smoking before 50 years of age, the risk of dying in the next 15 years is half that of a smoker. Even in persons who quit at 60 to 64 years of age, the risk of dying is reduced by 10% compared to persons who continue to smoke. There are enormous respiratory benefits. Smoking cessation is the most effective way to reduce the risk and improve prognosis of COPD.[1] Smoking cessation reduces the risk of developing cancer. Ten years after cessation of smoking, the risk of dying from lung cancer is about one-third to that of smoking persons. Smoking cessation also reduces the risk of acquiring a second primary cancer.[35]

The rate of decline in lung function in COPD among former smokers returns to that of never smokers. Smoking cessation also decreases the risk of influenza and pneumonia. If a mother stops smoking before becoming pregnant or within three to four months of pregnancy, the birth weight of the infant will be the same as that of infants of nonsmokers. Even cessation at later stage of pregnancy will lead to higher birth weight than those of babies of regular smokers. Smoking cessation also eliminates the risk of passive smoking induced diseases, including pneumonias and exacerbations of bronchial asthma in relatives.[36]

SMOKING CONTROL INTERVENTIONS

Controlling smoking addiction is quite demanding and also unpredictable. A multitude of interventions have been tried with variable rates of success. Smoking cessation is defined as validated sustained abstinence from cigarettes and/or other tobacco products for at least six months, preferably for a year.[37]

The available smoking cessation interventions can be classified into behavioral, pharmacologic, combined and alternative methods. Behavioral interventions are physician guidance, individual counseling and group counseling, or counseling by telephone. Pharmacologic interventions include Nicotine Replacement Therapy (NRT), sustained-release bupropion, varenicline as first-line agents and clonidine and nortriptyline as second-line agents. The alternative, less evidence based, interventions are hypnosis, acupuncture, aversive therapy, exercise, lobeline, anxiolytics, mecamylamine and silver acetate. Nicotine vaccine is among some of more promising agents for future therapy of tobacco dependence. Above all, it is most important to prevent the initiation of smoking in unexposed individuals.

How to Restrict Tobacco Use in the Society: First Level Prevention

Smokers may be divided in two categories children and adolescents in the first group and grown-up adults in the second group. They may be further classified as sick and healthy smokers.

Children and Adolescents

They belong to the age group when a smoker learns smoking. Efforts should be made to make these children aware of harmful effects of smoking. It is easy not to start than to quit smoking. Pamphlets, stickers, articles in newspapers, television serials and a chapter in curriculum books may play an important role in dissuading adolescents from initiating smoking. In a recent study, use of posters; curriculum changes; parental involvement and peer-led activism reduced self-reported tobacco use, as well as future intentions to start tobacco chewing or smoking.[38]

Grown-up Adults

Usually grown-up nonsmoker adults are unlikely to initiate smoking in later years of life. They are probably most receptive in accepting dangers of passive smoking and therefore must be motivated to resist anyone else smoking in their presence. Efforts should be made to make these people aware that breathing clean air is very important for health. It will ensure the compliance of ban on smoking at public places.[39]

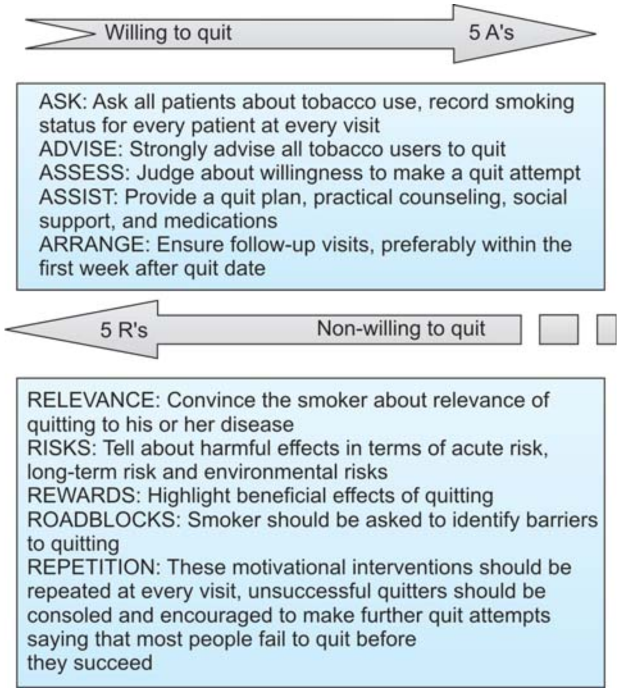
Sick Smokers

Sick smokers can be motivated more readily. Appropriate advice by health care workers can motivate a sick smoker for cessation of smoking. Timely advice by doctors, nurses, pharmacists and other health care personnel is crucial for a smoker who is interacting with them during his illness. Current evidence-based opinion regarding smoking cessation is that it should be done for every smoker during every health care visit.[40,41] Even a short period of counseling at the clinician's office, to ask a smoker to quit, results in cessation rates of up to 10%.[42,43]All smokers including those at risk for COPD already having disease should be offered the most possible and rigorous cessation intervention. The rate of successful smoking cessation at one year is 7% to 16% if the smoker undergoes behavioral intervention alone and up to 24% when receiving pharmacological treatment plus behavioral support.[44]

Healthy Smokers

Healthy smokers are least receptive to no-smoking advice. However, their tobacco use can be restricted by means such as making cigarettes more expensive, ban on public smoking and ban on sale to minors. Sometimes, peer pressure, family persuasion and religious appeal may motivate smokers in this category.

Efforts must be made to register the smokers for subsequent detailed interventional plans. This form of counseling takes less than 10 minutes of clinicians. For such brief intervention used to initiate smoking cessation, a mnemonic five "A's" is commonly used. All patients



ASK: Ask all patients about tobacco use, record smoking status for every patient at every visit
ADVISE: Strongly advise all tobacco users to quit
ASSESS: Judge about willingness to make a quit attempt
ASSIST: Provide a quit plan, practical counseling, social support, and medications
ARRANGE: Ensure follow-up visits, preferably within the first week after quit date

RELEVANCE: Convince the smoker about relevance of quitting to his or her disease
RISKS: Tell about harmful effects in terms of acute risk, long-term risk and environmental risks
REWARDS: Highlight beneficial effects of quitting
ROADBLOCKS: Smoker should be asked to identify barriers to quitting
REPETITION: These motivational interventions should be repeated at every visit, unsuccessful quitters should be consoled and encouraged to make further quit attempts saying that most people fail to quit before they succeed

Fig. 88.5: Initiation of smoking cessation effort [43,45]

should be **asked** about tobacco use and their smoking status is recorded. A strong **advice** is given to all tobacco users to quit. Their willingness to make a quit attempt is **assessed**. The smokers are **assisted** with a quit plan, practical counseling, social support and medications. Finally, follow-up visits are **arranged** for the smokers willing to quit. For those smoker not willing to undergo cessation, five "R's" are used to enhance motivation and decrease mental inertia to quit: Relevance, Risks, Rewards, Roadblocks and Repetition (Fig. 88.5).[45]

Behavioral Interventions

Initial approaches to smoking cessation during mid 20th century were based on the behavioral therapy alone. For next few decades, cognitive therapy gained momentum but finally pharmacotherapy started emerging around 1990s. Behavioral interventions are effective in smoking cessation, although there is insufficient information to know which elements of behavioral support or type of approach (like motivational interviewing or cognitive behavioral therapy) is more effective.[40]

Basically, three behavioral interventions approaches are utilized: 1) Practical counseling- problem solving or skill training, 2) Giving intra treatment support, 3) Provision of extra treatment support. The physician, nurse or telephone counselor may assist in the process or it is performed as self-help by the patient himself. Among the simplest of behavioral interventions, even brief, but direct physician advice to quit smoking is effective. Furthermore, the rate of smoking abstinence increases when the intensity of advice is increased and when follow-up visits are included.

Types of Behavioral Interventions

1. *Individual counseling:* A review of studies about individual behavioral counseling by trained therapists with a follow-up of at least six months indicated benefits of counseling as compared to no intervention. Individual counseling usually consists of one or more direct interview sessions, often followed by telephone contact for the support.[19]
2. *Group counseling:* Available studies also suggest that group counseling is effective in promoting smoking cessation.[19,46] Overall, the evidence supporting the efficacy of group counseling satisfies level A.[46]
3. *Telephone counseling:* It is simple, can reach a large number of people at a time. Proactive telephone counseling, which the counselor initiates, is more effective than reactive counseling, which is client initiated.[19]
4. *Self-help information:* It is marginally beneficial for increasing smoking cessation.[19,46] Examples of self-help materials include booklets, leaflets, brochures, videotapes, compact discs, help lines, and various other computer and Internet interventions. Enhanced or tailored self-help material was associated with better cessation rate than standard self-help material.[47] Though the effectiveness is nominal, self-help also achieves evidence level A.[46] Other reasons that self-help, despite its small impact, should be included in smoking programs are increased population awareness, low expense and the opportunity to customize the message. Cessation programs available on the Internet are also found to be effective in smoking cessation.[48,49]

Increasing Effectiveness of Interventions

Another lesson from available meta-analyses of behavioral interventions is that adding cessation formats confers incremental effectiveness. Combining up to three to four formats, e.g. self-help with individual counseling or individual counseling and telephone counseling, may increase the absolute cessation rate by 12%.[46] Also, increasing the intensity of interventions enhances smoking cessation rates. Factors increasing effectiveness include the duration of each individual session, the total time spent in all sessions and the number of sessions.

With minimal counseling of up to three minutes, the cessation rate was 13.4%; with low-intensity counseling (3 to 10 minutes), the rate was 16.0%; with high-intensity counseling (more than 10 minutes), the rate was 22.1%.[46]

A review of the impact of the number of counseling sessions suggests that the greater the number of sessions, the greater the chance for cessation. Programs with 0 to 1 sessions had a quit rate of 12.4%, whereas those with more than eight sessions had a quit rate of 24.7%. [40] In another study Simon, et al. randomized 228 patients to either low- or high-intensity intervention, with all receiving NRT via patch; the one-year abstinence rate was significantly higher in the higher-intensity counseling group.[50]

Pharmacotherapy

Pharmacotherapy aimed to quit smoking is very different from that used for the treatment of a disease. Success of pharmacotherapy of quit smoking depends substantially on the desire or motivation of a patient. Pharmacotherapy fails to produce effect if the patient does not have a desire or motivation to quit. Unfortunately, we do not have any medicine to induce a desire to quit smoking. Personalized counseling to induce motivation for quitting smoking should be a prerequisite for the use of pharmacotherapy.

A number of meta-analyses have revealed that all current medications for smoking cessation are twice more efficacious than placebo.[51] However, there is limited data to guide clinicians to advocate one type of medication over another or the use of combinations. Lately, a Delphi method was used by a group of international experts for clinicians to guide the tailoring of medication for individual smoking cessation.[19] Levels of scientific evidence, patient preference, previous experience and failed attempts with monotherapy are some of the factors which should determine the prescription. Other important factors include the presence of comorbidities and contraindications to the medications.[1]

Current Medications for Smoking Cessation

All smokers who have previously relapsed when attempting to quit are questioned about their prior use of pharmacotherapy and their perceptions of the treatment options. Even light smokers or those who have failed in earlier attempts to give up, can benefit from pharmacotherapy.[52]

Besides decreasing the withdrawal symptoms and craving, pharmacotherapy decreases the short-term reinforcing effects of tobacco. This form of relief can help to ease the process of a patient learning new coping skills. The addition of a pharmacologic agent to a quit plan can have a positive psychological impact on those making quit attempts, especially if previous quit attempts had fared poorly (Table 88.2).[53,54] All first-line medications appear to similar effectiveness, but there have been few direct comparisons.

TABLE 88.2: Various medications for smoking cessation[50,51]

Type		*Requirements*	*Dose*	*Duration*	*Drawbacks*
NRT	Gum	Start on quit date	2 mg- up to 24 cigarettes/d 4 mg- >25 cigarettes/d	Up to 12 weeks	Mouth soreness, dyspepsia
	Patch	Start on quit date Worn 24 hours	21 mg, 14 mg, 7 mg depending on level of addiction	8 weeks	Insomnia, Local skin reaction
	Inhaler	Start on quit date, inhaled into mouth, not lungs	6 to 16 cartridges/d	Up to 6 months	Local irritation of mouth and throat
	lozenge	Start on quit date	2 mg- 1st cigarette > 30 min, post-awakening 4 mg- 1st cigarette < 30 min, post-awakening	8 weeks	Mouth soreness, dyspepsia
Bupropion SR			150 mg OD for 3 days then 150 mg BID for rest of treatment	Up to 6 months	Insomnia, dry mouth, contraindicated in seizures
Varenicline		Quit date two weeks after initiation Taken after meals with a full glass of water	0.5 mg OD for 3 days, 0.5 mg BID for next 4 days then 1 mg BID for rest of treatment	12 weeks treatment and 1 week maintenance	
Clonidine		Quit date one weeks after initiationTaken after meals with a full glass of water	0.15 to 0.75 mg /d	3 to 10 weeks	Dry mouth, dizziness, drowsiness, sedation, rebound hypertension
Nortriptyline		Quit date two to three weeks after initiation. Taken after meals with a full glass of water	75 to 100 mg/d	12 weeks	Dry mouth, sedation, risk of arrhythmia

The medication is selected on the basis of: Medical conditions, potential adverse effects, individual preference, previous smoking cessation, level of dependence and any apprehension of weight gain. Current medications may be grossly divided into nicotine replacement therapy and non-nicotine pharmacotherapy.

A. Nicotine Replacement Therapy

Nicotine replacement therapy is the most common medication to assist smoking cessation, probably because there are more data available on its effectiveness and safety.[53] It is important to explain to the patient that NRT will help diminish nicotine craving, will make it controllable but will not completely eradicate.

Rationale: Nicotine is the substance to which a smoker is addicted. In smokers, when the blood level of nicotine decreases, withdrawal symptoms begin within a few hours after having the last puff of smoke. Smoking relieves these symptoms immediately. If smoking is not done, withdrawal symptoms will continue to manifest with increasing severity. Nicotine replacement therapy will maintain a stable nicotine level in the bloodstream of the smoker, who is trying to quit, avoiding withdrawal symptoms.[55] When NRT via transdermal patch is used, more constant delivery of nicotine helps to desensitize nicotine receptors and therefore further inhibit withdrawal symptoms. Nicotine replacement therapy is available in form of nicotine gum, patches, lozenges and inhalers. In tobacco chewers, nicotine gum may be more effective since it provides the physical sensation of manipulating tobacco in the mouth.

A recent systematic review of randomized clinical trials including smokers not ready to stop, reveals that with NRT, twice as many quitters achieve six months of sustained abstinence.[56] It is also shown that the nicotine patch used along with another NRT is more effective than any of the single NRT.[57] It is customary to equate 1 mg of NRT to each cigarette smoked and start two weeks prior to the quit date while the patient goes on smoking on NRT. However, both these practices are not based on sound scientific evidence. Ideally, smoking should be stopped before starting NRT.

1. *Transdermal nicotine patch:* It is the most common form of NRT, which has been available for more than two decades. It is available in different strengths but 21-mg patch over a 24-hour period is commonly used. Current trend involves increasing the NRT patch dosage and duration for heavy tobacco users. The final goal is to supply the dosage necessary to equate the nicotine level to body's accustomed state. Side effect may consist of local irritation, headache, dizziness, nausea and sleep disturbances.
2. *Nicotine gum or lozenge:* They contain polacrilex compounds that are resin carriers. Both forms (gums and lozenge) of polacrilex are sugarless and available in different flavors. One should not eat or drink just before and during the use of these compounds. Acidic food and drinks like coffee or carbonated beverages interfere with drug delivery by these compounds, hence best avoided. Side effects of nicotine gum include dyspepsia, hiccups and mandible pain.
3. *The nicotine inhaler:* Unlike the usual pressurized metered-dose inhaler, nicotine inhaler is a cartridge, from which, on suction a nicotine vapor is released in mouth and throat. For heavy tobacco users, it is not a good option as a monotherapy because of its poorer dose delivery. To deliver high doses, nicotine nasal spray can be used, but it is not popular as it is costly and can cause substantial nasal and eye irritation. Nicotine replacement therapy is usually considered safe for most patients[53,58]

Contraindications to NRT's

Nicotine replacement therapy should not be started if within the past six weeks there is a history of myocardial infarction, unstable angina, uncontrolled hypertension, hypertension during treatment and severe rhythm disturbance. Relative contraindications include severe COPD, uncontrolled diabetes mellitus, and some cardiovascular disorders like coronary artery disease. Vivid dreams or insomnia may indicate a high NRT dose. Nicotine replacement therapy may interact with other drugs; it can lead to an increase in blood pressure when used along with bupropion. Drugs taken concomitantly, like insulin, benzodiazepines, caffeine and ergot may need dose adjustment. Irritation at application-site may suggest a need for a change in type of NRT. Insomnia with NRT is dealt by removing patch one hour prior to bedtime or by reducing the dose. Sublingual tablet is a new form of NRT, but the superiority of this formulation over NRT lozenge has not been proved.[59]

B. Non-nicotine Pharmacotherapy

1. *Bupropion:* Bupropion can reduce the severity of nicotine cravings and withdrawal symptoms. It was originally introduced in 1997 as a smoking cessation aid. Now it has been approved in more than 50 countries across the globe.[60] The proposed mechanism of the effectiveness of bupropion in smoking cessation is blockade of the reuptake of dopamine and norepinephrine.

For tobacco dependence treatment, sustained release variety of bupropion is preferred over the instant release. Bupropion SR needs to be taken twice daily and bupropion XL only once daily.

Side effects: Most common adverse effects of bupropion are dry mouth and insomnia. Agitation is an adverse effect that can be mostly avoided by the gradual escalation of dose from 150 mg to 300 mg daily by one week rather than just three days. Duration of treatment is typically 7 to 12 weeks with no tapering. The risk of seizures (one-in-a-thousand) is more common in epilepsy and some eating disorders. In a dose of 450 mg in treating depression, bupropion increases the risk of seizures, but the 300 mg dose used for tobacco cessation has very little risk of seizure. Bupropion should not be used by people with active use of alcohol who take more than three drinks per day or by people with sudden alcohol withdrawal. It should also not be used by pregnant women. One significant advantage of bupropion is that it typically does not cause weight gain, may rather suppress it.

2. *Varenicline:* Varenicline is an effective oral smoking cessation product to be approved by the US Food and Drug Administration. It was launched in mid-2006 in some parts of the world and was launched in India in 2008. Several trials have shown the benefits of varenicline in cessation rates. Bupropion was compared with varenicline in recent randomized controlled trials. In a meta-analysis it was found that rates of smoking cessation associated with varenicline were superior to those of bupropion and NRT.[61-63]

   Varenicline acts as a partial agonist of the $\alpha_4\beta_2$ nicotinic acetylcholine receptor through which nicotine dependence is mediated. It also stimulates the dopaminergic system, which results in reduced withdrawal symptoms. The drug also blocks nicotinic receptors, which prevents the dopamine release in response to nicotine. Additionally, reinforcing effects of nicotine exposure is blocked because varenicline is expected to occupy this receptor.[64]

   The current recommendation states that the drug should be started one week prior to quit date, the full therapeutic effect may not occur until following a few weeks.

   Side effects: The most common side effect of varenicline is nausea occurring in about 30 percent of patients. The nausea is generally short-lived, taking varenicline with a full glass of water and after eating helps to reduce this unfavorable effect. Less common side effects are insomnia, abnormal vivid dreams, constipation and flatulence.[53]

   Varenicline has been associated with some psychiatric adverse effects. These include erratic behavior, new appearance of depressed mood, agitation, suicidal ideation, suicidal attempts and completed suicides within days to weeks after initiating varenicline.

   Patients should be asked about any prior history of mental illness before starting varenicline and monitoring for changes in mood and behavior. It is important to note that in clinical trials, prevalence of behavioral changes with varenicline were similar to those with placebo. Varenicline poses a low burden on the kidney and liver, therefore may be used in end-stage renal disease with a reduced dosage.

C. Second Line Drugs

1. *Nortriptyline:* Nortriptyline is a second-generation tricyclic antidepressant used in the treatment of major depression. It is recommended as a second-line medication in recent guidelines for the treatment of tobacco dependence.[53,59,65] Nortriptyline can have a sedating effect, it is more practical to take it in the evening. There are a number of other potential adverse effects including dizziness, blurring of vision, tinnitus, tremor, weakness, insomnia, nausea, constipation and rash. In patients with cardiovascular disease, it can increase the risk of serious dysrhythmia.[59] Nortriptyline can interact with a variety of medications. It is usually started earlier than other tobacco cessation medications, i.e. up to three weeks prior to quit date, to allow for a gradual build of dosage.
2. *Clonidine:* Clonidine, also a second-line tobacco-cessation drug, is effective in reducing symptoms of opioid and alcohol withdrawal.[59] It can be taken orally in tablet form or via transdermal patch, and is started a week prior to quit date. Possible adverse effects include drowsiness, dizziness, fatigue, agitation, depression, constipation, nausea, weight gain and rebound hypertension.[53] A specific dosing regimen for tobacco cessation has not been established and there are several important drug interactions.

D. Combination Treatments

Nicotine patch can be combined with other formulations of NRTs in the cases of heavy addiction. Bupropion or varenicline should not be combined together or theoretically, with any of NRTs, no sound evidence is available for such an approach. They also should not be given to children, pregnant or lactating mothers. However, both of these can be used safely for people with stable cardiovascular disease.

Any of above pharmacological therapy may be advantageously combined with all types of behavioral interventions.[66]

E. Novel Therapies: Hope for the Future

We have seen that drug therapy for smoking is effective, but a significant number of patients fail to gain significant advantage on a long-term basis. Therefore, there is a continuous need for search of an agent, which would be ideal to tackle this problem more effectively. Agents which are of some hope include new non-nicotine replacement medications such as selegiline, fluoxetine and naltrexone.[19,67]

Newest strategies are related to search for a vaccine against nicotine addiction and application of pharmacogenetic principles to smoking cessation. A safe and effective vaccine would lead to better compliance than the existing pharmacotherapy. Such a proposed vaccine is based on stimulation of immune system to form specific antibodies (Nic-IgG) to nicotine to make the molecule too large to cross the blood-brain barrier and act on its central receptors.[68-70]

Nicotine is principally metabolized by cytochrome-450 enzyme coded by CYP2A6 gene. Fast metabolizers need high amount of nicotine to maintain the addiction, and hence chance of high level addiction. Original Text Various other genes related to signaling molecules and CYP2B7P1/CYP2B6 gene responsible for bupropion metabolism are under evaluation. With better knowledge of pharmacogenomics, we will be able to design the medication for individual patients better.

CONCLUSION

Tobacco smoking is responsible for enormous adverse respiratory health consequences. Smoking cessation interventions are rewarding and should be attempted for all patients and at every health care visit. Effective and relatively safe pharmacotherapy in the form of first-line drugs like NRT, bupropion and varenicline are now available all over the world. India and other developing countries have started developing an antismoking momentum that needs to be build up with greater force by health care providers, supported by better responsiveness of smoking individuals. Tobacco cessation clinics and self-help material, including the information books on the subject are now widely available.[71] World Health Organization with its resolve to create smoke free and tobacco free world has taken several steps towards accomplishing the ultimate goal of a smoking-free society.

Pulmonary Rehabilitation

Rachael A Evans, Roger S Goldstein

SYMPTOMS AND DISABILITY ASSOCIATED WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

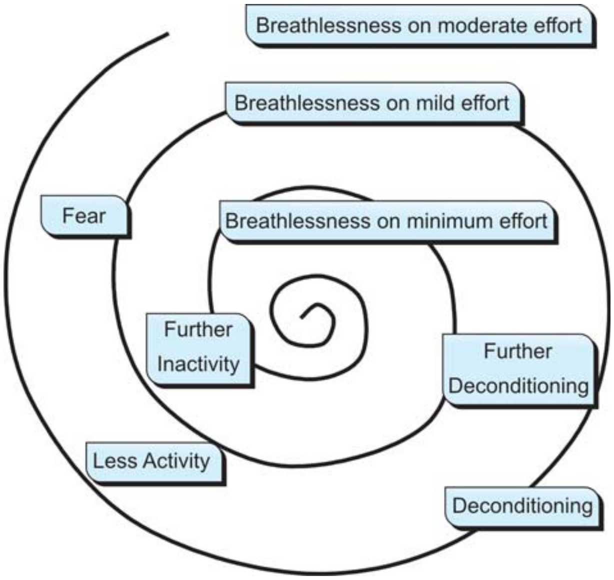
Patients with chronic obstructive pulmonary disease (COPD) commonly present with exertional breathlessness and fatigue[1] and typically they become less active to avoid these symptoms. This reduction in activity can lead to loss of confidence, depression, loss of work or inability to perform hobbies and social isolation, resulting in substantial disability. Although the primary pathological process of COPD results in a progressive reduction in airflow, the correlation between the degree of lung function impairment and the severity of symptoms is weak. Abnormalities in gas exchange, as well as the restrictive ventilatory limitation associated with hyperinflation contribute to the symptoms of exertional breathlessness and diminished exercise capacity.

Systemic Consequences of COPD

In addition to the primary pulmonary pathology, there are secondary alterations in skeletal muscle function, nutrition, bone density, gonadal hormones, hemoglobin and mood,[2-4] many of which influence exercise tolerance and health-related quality of life. The skeletal muscles of locomotion are altered on multiple levels. Morphologically, there is a reduction in muscle mass and strength of the quadriceps compared to age-matched healthy controls.[5] The muscle fiber types are altered with an increase in the proportion of the type IIX, fast twitch, glycolytic fibers (more fatigable) compared to the type I, slow twitch, oxidative fibers.[6] Muscle metabolism is altered, with a reduction in oxidative enzymes and a reduction in mitochondrial density. Energy metabolism during exercise is altered with a more rapid loss of phosphocreatine at lower workloads than age matched healthy controls and a failure of ATP replenishment to meet the demand.[7]

Skeletal muscle dysfunction contributes to reduced exercise tolerance by promoting an earlier rise in the level of lactic acid, which when buffered, increases CO_2 production, which in turn, increases the ventilatory load applied to a system, which already has an impaired ventilatory capacity. Whether the skeletal muscle dysfunction relates to deconditioning or whether it relates to an underlying inflammatory myopathy, remains an area of interest. Although people with COPD do enter a vicious circle of inactivity (Fig. 89.1), which influences the function of the leg muscles, muscles not involved in ambulation, such as the adductor pollicis retain normal function. Moreover, much of the reduced ambulatory muscle function can be reversed with exercise training. In favor of an underlying systemic inflammatory process are the increased levels of systemic markers of inflammation, as well as oxidative stress and nutritional depletion. Hypoxia and medications, such as corticosteroids also contribute towards the skeletal muscle alteration.

The spiral of inactivity is also affected by the symptoms of anxiety and depression experienced by many patients with COPD. The sensation of dyspnea generates feelings of anxiety, but anxiety itself can manifest as dyspnea. Low mood is frequently reported by patients with COPD related to their disability and loss of function, but may also be a preexisting phenomenon



Breathlessness on moderate effort

Note: The diminishing cycle of dyspnea and reduced exercise tolerance.

predisposing to smoking. Unfortunately, the effect of low mood on motivation and self-esteem further impact on inactivity.

THE ROLE AND DEFINITION OF PULMONARY REHABILITATION

The term "rehabilitation" refers to the process of restoration of function despite physical or psychological disability. Pulmonary rehabilitation (PR) programs have developed over the last few decades as a therapy targeted at the secondary alterations of COPD, aiming at improving both the functional and psychosocial aspects of an individual. It is now recommended as an integral part of the clinical management of patients with COPD and has a strong, supportive evidence base demonstrating a reduction in dyspnea, and improvements in both exercise tolerance and health-related quality of life.[8] There is also evidence to support a reduction in health care costs following a rehabilitation program.[9] It has yet to be established whether PR impacts directly on mortality, although it clearly impacts on many of the factors that affect mortality, such as dyspnea, exercise tolerance and health-related quality of life.[10,11]

The international guidelines of the American Thoracic Society (ATS) and the European Respiratory Society (ERS) adopted the following definition for Pulmonary Rehabilitation; "It is an evidence-based, multidisciplinary, and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities. Integrated into the individualized treatment of the patient, pulmonary rehabilitation is designed to reduce symptoms, optimize functional status, increase participation and reduce health care costs through stabilizing or reversing the systemic manifestations of the disease."

TABLE 89.1: Key features of a pulmonary rehabilitation program

- Assessment for suitability and safety
- Provision by a multidisciplinary team
- Individually prescribed exercise training combined with education and self-management advice
- Minimum of two supervised and one unsupervised sessions per week
- Exercise sessions each of 20–30 minutes duration
- Minimum of six weeks duration
- Individual progress assessed by appropriate outcome measures usually exercise performance and health status
- Audit for quality control
- Ideally to have a subsequent maintenance program or potentially further programs after an exacerbation

Pulmonary rehabilitation programs include several evidence-based components and should not be mistaken for more general programs of activity promotion, convalescence or pure self-management programs. It is an organized, multidisciplinary approach with defined, essential features (Table 89.1).

The Changing Pulmonary Rehabilitation Population—Who to Refer?

Patients with COPD are the traditional target population for pulmonary rehabilitation and work in this population has informed the original studies. However, the spiral of inactivity also applies to other chronic respiratory diseases; providing a rationale for rehabilitation which has been reported to be beneficial in other conditions including pulmonary fibrosis, post-tuberculosis lung disease, thoracic restriction, bronchiectasis, cystic fibrosis, asthma, pulmonary hypertension, pre and post-operatively for lung resection, volume reduction or transplantation (Fig. 89.2). Certain program adaptations for non COPD patients are required, such as the exclusion of exercise-induced arrhythmias in pulmonary hypertension and education about chest clearance for patients with chronic suppurative lung diseases.

The predominant clinical inclusion criterion, for referral to pulmonary rehabilitation, is exertional dyspnea that interferes with function as assessed by the Medical Research Council (MRC) Dyspnea Scale (Fig. 89.3). This is a simple, self-assessed scale and can

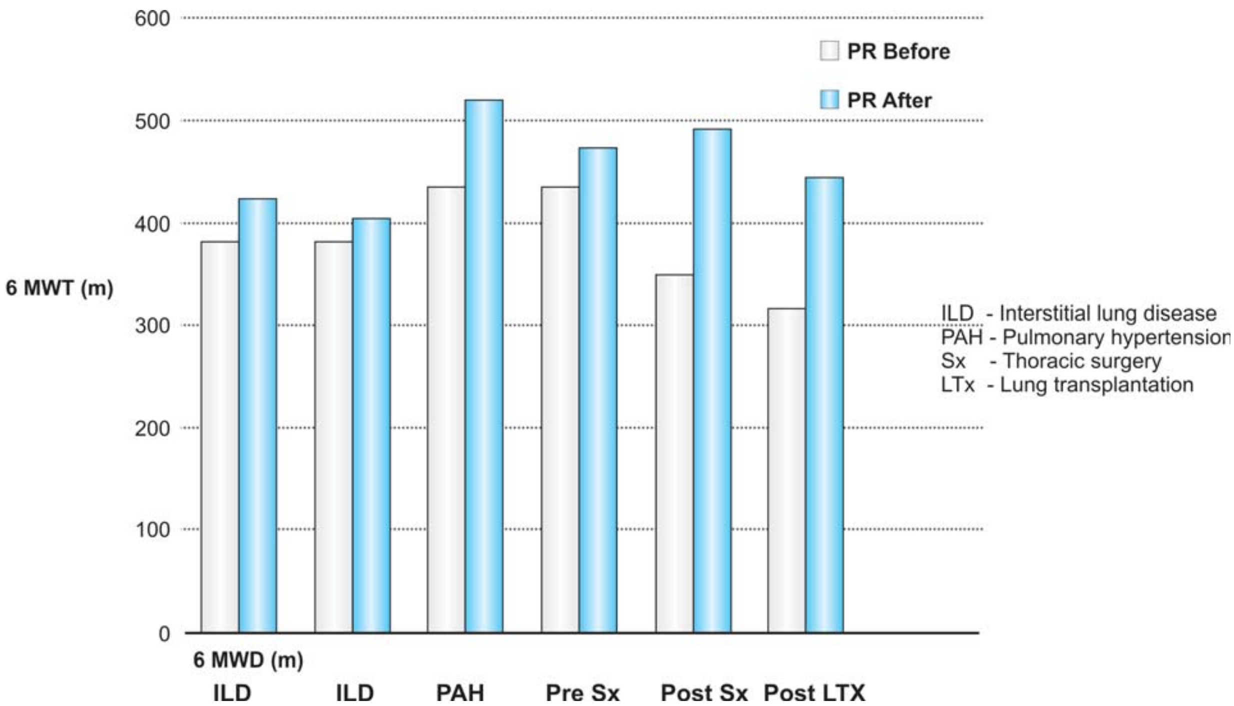

Fig. 89.2: Six-minute walk test distance before and after pulmonary rehabilitation in different population
Note: Similar increments in 6 MW test can be achieved among a variety of respiratory populations[9]

easily be used to screen those who may benefit from rehabi-litation. International guidelines suggest referral for pulmonary rehabilitation for Grades III–V. There is evidence to suggest that patients with the milder levels of breathlessness may also benefit.[12] The World Health Organization (Global initiative for Obstructive Lung Disease) recommends rehabilitation for any symptomatic patients with GOLD stage II and above (FEV_1 <80% predicted).

Both the primary respiratory disease and existing comorbid conditions should be optimally managed prior to enrolment. Patients with obstructive disease should receive optimal airway care. Any preexisting depression should be addressed as it is known to be associated with poor compliance and response to rehabilitation. Diagnostic assessment and optimizing management should occur prior to commencing PR.

Grade	Description of Limitation
I	I get breathless only with strenuous exercise
II	I get breathless when hurrying or walking uphill
III	I walk slower than people of the same age on the level or I have to stop because of breathlessness on the level
IV	I can only walk 100 yards before stopping because of breathlessness or after a few minutes on the level
V	I am breathless when dressing or undressing or I am too breathless to leave the house

Fig. 89.3: The Medical Research Council (MRC) Dyspnea Scale[7]

Patients need to be able to participate in endurance exercises and those with a predominantly orthopedic, neurological or peripheral vascular limitation to exercise are commonly excluded. Safety criteria should be adhered to, for example, a myocardial infarction sustained within three months, unstable angina, moderate-to-severe aortic stenosis or uncontrolled blood pressure would all exclude patients from being enrolled. Patients with unstable cardiovascular disease must be assessed and treated appropriately prior to inclusion to a program. Nonclinical factors may be pivotal. These include a reasonable level of comprehension, realistic expectations of the program, motivation to improve, an ability to follow instructions, acceptable health literacy and a supportive home and family.

Components of a Pulmonary Rehabilitation Program

Assessment

The assessment should systematically address the inclusion and exclusion criteria and further inform the patients about the process of pulmonary rehabilitation.

An assessment of dyspnea, exercise performance and health status is standard and can inform both individual progress and program quality.[13] An exercise assessment for the program exercise prescription, requirements for safety and as a baseline for the exercise outcome, is increasingly performed using simple, inexpensive field tests rather than expensive laboratory-based exercise equipment. Patients with resting hypoxia should exercise with supplemental oxygen. The criterion for ambulatory oxygen varies among jurisdictions. Those who desaturate markedly on exercise <85% are often offered supplementary oxygen during training. In many countries, the expense of oxygen makes it prohibitive except in patients with profound hypoxemia.

Outcome Measures

Full cardiopulmonary exercise tests: The gold standard measurement of exercise capacity is peak oxygen consumption. A maximal, incremental, symptom limited cardiopulmonary test with expiratory gas analysis can provide this, as well as comprehensive information about the precise limitation to exercise (Fig. 89.4). However, it involves expensive equipment and expertise. Typically tests are performed on a cycle ergometer providing a stable platform, but a treadmill can also be used particularly if cycling is not familiar. Endurance tests can be performed using the same equipment set at an intensity relative to the peak performance. Although the variability of endurance testing is greater than for maximal testing, endurance tests are often a more sensitive outcome measure for pulmonary rehabilitation.

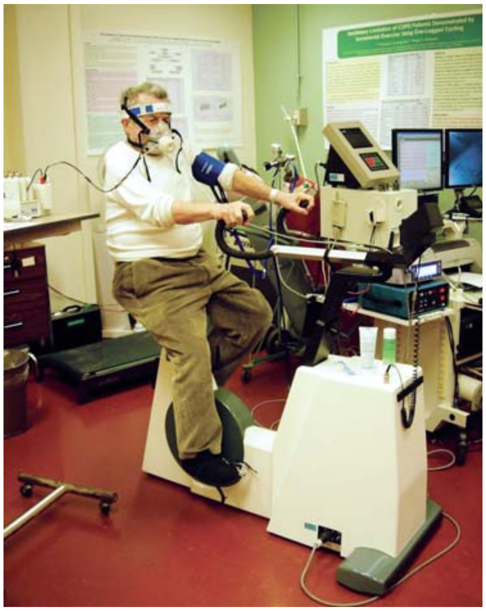

Fig. 89.4: Cardiopulmonary exercise test on a cycle ergometer

Six-minute walk test: The most commonly used field test is the six-minute walk test (6MWT).[14] The test is completed over a 30 meter flat course. It is self paced and standardized instructions are given. Patients are asked to walk as far as they can for six minutes and the result is usually presented as the distance walked, although the speed can be calculated. The test is reproducible after two practice tests and is responsive. Unlike other field tests normal reference values are available. The six minute walk test can be influenced by encouragement, which is therefore standardized. It is likely closer to peak exercise capacity although the distance walked is referred to as a measure of functional capacity. The six minute walk test distance is highly correlated with the other outcomes of COPD, such as mortality and is featured in the multidimensional severity index; the BODE index.[15] It has been used to set exercise prescription (usually as a percentage of the overall speed), but the intensity will vary between individuals. It is reliable, valid and interpretable, all important qualities for its use in clinical research[14] (Fig. 89.5).

Incremental shuttle walk test: The incremental shuttle walk test (ISWT) is a symptom limited, externally paced test, conducted along a 10 meter course (Fig. 89.6) and reflects maximal exercise capacity.[16] The walking speed increases every minute until the patient is too breathless or fatigued to continue or can no longer maintain the required speed. The result is presented as the total distance achieved. It

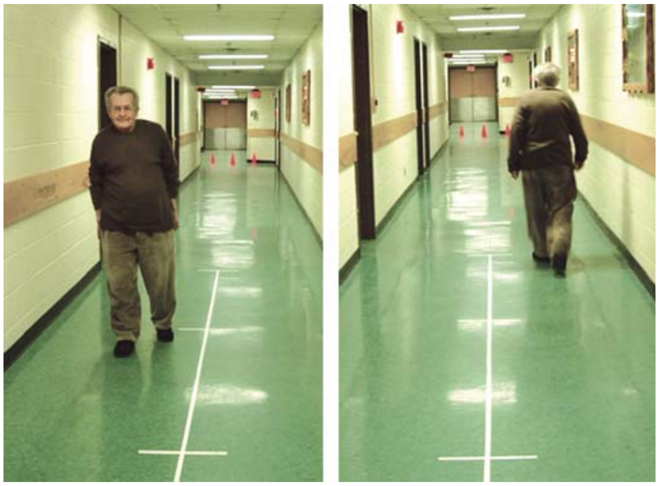

Fig. 89.5: Six-minute walk test

Note: This is carried out on a flat surface in a temperature and humidity controlled environment

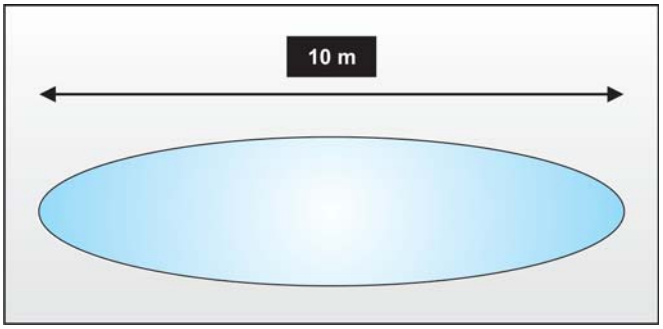

Fig. 89.6: Diagram of the shuttle walking course

is reproducible after a single practice test. In contrast to the six minute walk test the ISWT has a graded physiological response. However, normal reference values are not currently available. The test is also reliable, valid and interpretable,[16,17] making it an excellent evaluative test just like the 6MWT.

Endurance shuttle walk test: The endurance shuttle walk test (ESWT) was developed as a test of submaximal exercise capacity. It is similarly symptom limited, externally paced and uses the same 10 meter course as the ISWT.[18] After a two minute warm up, the patients walks at the set speed until they can no longer maintain the required speed or are too breathless or fatigued to continue. The result is presented as the time walked after the warm up and is reproducible after a familiarization test. The ISWT and ESWT can be used to develop individualized exercise prescriptions for pulmonary rehabilitation. The speed of the walk can be set at a high intensity (85% of the predicted peak oxygen consumption) derived from the ISWT distance. The duration of the walk can then be progressed throughout the program. Both the ISWT and ESWT are responsive outcome measures.

Health status: Health-related quality of life (HRQL) has become an important outcome for assessing chronic disease interventions. Most disease-specific questionnaires have components that assess dyspnea and activity limitation. The two most commonly used and therefore the best understood are the Chronic Respiratory Questionnaire (CRQ)[19] and St George's Respiratory Questionnaire (SGRQ).[20] They are both reproducible and evaluative, but the SGRQ has the advantage of also being discriminative. Generic questionnaires, such as the Medical Outcomes Short Form-36 Questionnaire (SF-36) can also be used. This has the advantage of being able to compare across different disease population and has normative values, but it is more discriminative than evaluative and may not identify small disease specific changes.

Dyspnea

The MRC scale is often used as an outcome measure for dyspnea. It is a valid, reproducible instrument, but not designed to be an evaluative tool. It is, however, a valuable guide to staging the severity of COPD. The Baseline Dyspnea Index and the Transition Dyspnea Index (BDI/TDI) are disease specific valid, reproducible and interpretable. Together with the SGRQ and the CRQ, the BDI-TDI is among the most frequently employed measures of outcome in PR.[21]

Clinical Important Difference

For many of the outcome measures described a "clinically meaningful" change has been evaluated. This adds to clinical interpretation of results from an intervention. A minimum clinically important difference exists for the 6MWT, ISWT, ESWT, CRQ, SGRQ and the BDI/TDI. If achieved, it provides a rationale for introducing or withdrawing a management intervention.

Core Components of a Pulmonary Rehabilitation Program

Core components of a pulmonary rehabilitation program are shown in Table 89.2.

Exercise Training

Exercise training is an essential component to pulmonary rehabilitation and has the largest supporting evidence base of all the other components.

Lower limb endurance training: Lower limb endurance training is mandatory for individuals who wish to improve exercise tolerance and reduce dyspnea on exertion. It is individually prescribed, based on an assessment exercise test and progressed throughout the program. High-intensity training is recommended in the healthy population for achieving cardio-respiratory fitness. Similar principles apply to patients with COPD and high-intensity training produces greater physiologic benefits than lower intensity training.[22] However, many are so constrained by dyspnea that they are often unable to achieve the ideal training intensity, but the highest

TABLE 89.2: Core components of a pulmonary rehabilitation program

- Exercise training
  – Lower limb endurance training
  – Lower and upper limb resistance training
- Multidisciplinary education
- Psychological support
- Self-management

intensity feasible should be the aim. The training schedule should detail the intensity, duration and frequency of training. Intensity can be prescribed from the cardiopulmonary exercise (CPX) test performed on a treadmill or a cycle ergometer, or from the various field tests. The training speed or load can be calculated from the measured (CPX) or predicted (field tests) percentage of peak oxygen consumption (typically 60 to 80% for high intensity) or from peak heart rate (similarly 60 to 80% predicted for high intensity).

An exercise session should last between 20–30 minutes. Walking and cycling are both effective training modalities. Although interval training has a good rational for allowing the symptoms to recover during the lower intensity periods, studies have not identified interval training as being more effective than constant load training for those with COPD.

Resistance training: Resistance (strength) training has received much attention over the last two decades and is recommended by international guidelines. Although muscle strength is improved compared to endurance training alone, this has not translated to additional improvements in exercise tolerance or health status. The effect of strength training on daily physical activity has yet to be thoroughly investigated. Ideally, resistance training should be individually prescribed, for example at 40 to 60% of the one repetition maximum, and progressed through the program. The studies advocating resistance training were performed on gym equipment (Fig. 89.7). Lower limb exercise often consists of sit to stand, step ups, leg raises, which can be progressed throughout the program, but these exercises have not been thoroughly evaluated. Ankle weights can also be employed to add resistance.

Upper limb resistance training is commonly performed using free weights and currently unsupported endurance exercises are recommended in the guidelines. There are theoretical reasons why improving upper limb strength may help dyspnea and activities of daily living, but the results of small studies so far are varied.[23] Nevertheless, most pulmonary rehabilitation programs include upper limb exercises.

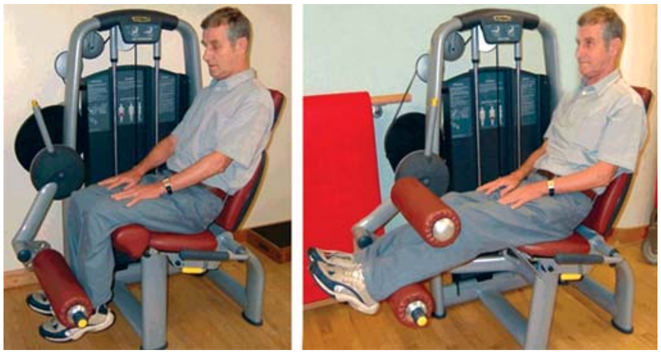

Fig. 89.7: Lower limb resistance training

TABLE 89.3: Example of topics for the education component

Multidisciplinary Education

- Exercise
- Nutritional advice
- Relaxation
- Devices and oxygen therapy
- Benefits advice
- Energy conservation
- Travel
- Sexual intercourse advice
- Disease education
- Pharmacology

Multidisciplinary Education (Table 89.3)

It is widely accepted that education is a logical and necessary component of pulmonary rehabilitation, but less is known about which topics are essential. Examples of typical education topics are shown in Table 89.2. Education is commonly delivered in a group setting, but should be supplemented with individual support and other ongoing educational materials, such as computer-based and online learning modules. Psychological support is a core component of pulmonary rehabilitation as many patients experience symptoms of anxiety or depression. Psychological status should be first assessed using a standardized measuring tool, such as the Hospital Anxiety and Depression Scale (HADS).[24] Support is usually delivered by the rehabilitation team, but for some patients with more severe symptoms a psychologist is consulted. The process of pulmonary rehabilitation has been shown to improve low mood and reduce anxiety.[25]

Education—Self-management

Self-management can be taught within or outside of pulmonary rehabilitation.[26] It increases patients' involvement and control of their disease and improves their sense of well-being. It has been shown to reduce resource utilization, especially that attributable to unscheduled visits to the hospital. Patients learn to cope and react to their disease. With new skills of decision making, early symptom recognition and action plans (Fig. 89.8), patients are able to recognize and respond to respiratory exacerbations and avoid hospital admissions. Exercise, nutritional management and the correct administration of medications are all assisted by self-management education.

Patient's copy

I FEEL WELL

MY SYMPTOMS

- I feel short of breath: ______________________
- I cough up sputum daily. No Yes, colour: ____________
- I cough regularly. No Yes

I FEEL WORSE

MY SYMPTOMS

- **I have changes in my sputum (colour, volume, consistency),** not only in the morning
- **I have more shortness of breath than usual**

Note that these changes may happen after a cold or flu-like illness and/or sore throat.
Some people feel a change in mood, fatigue or low energy prior to a flare-up.

MY ACTIONS

- I use my **prescription for COPD flare up**
- I avoid things that make my symptoms worse
- I use my breathing, relaxation, body position and energy conservation techniques
- If I am already on Oxygen, I use it consistently and increase from ___ L/min to ___ L/min
- I notify my contact person __________ (Tel:____________) and/or see my doctor (Tel:____________)

PRESCRIPTION FOR COPD FLARE-UP

1) If your SPUTUM becomes yellowish/greenish

start Antibiotic ____________ **Dose:**___ **#pills:**___ **Frequency:**___ **#days:**___

if repeating antibiotics within 3 months, use the following antibiotic instead

start Antibiotic ____________ **Dose:**___ **#pills:**___ **Frequency:**___ **#days:**___

2) If you are more SHORT OF BREATH than usual, take ___ puffs of _________ up to a maximum of ___ times per day, as necessary

If your SHORTNESS OF BREATH DOES NOT IMPROVE,

start **PREDNISONE** ____________ **Dose:**___ **# pills:**___ **Frequency:**___ **# days:**___

Physician Name	Signature	License	Date

I FEEL MUCH WORSE OR IN DANGER

MY SYMPTOMS	MY ACTIONS
• My symptoms have worsened. • After 48 hours of treatment my symptoms are not better.	• I notify my contact person and/or see my doctor • After 5 pm or on the weekend, I go to the hospital emergency department (Tel:____________)
• I am extremely short of breath, agitated, confused and/or drowsy, and/or I have chest pain	• **I dial 911 for an ambulance to take me to the hospital emergency department.**

Important Information: Make a follow-up appointment with your doctor to periodically review your plan of action or if you need to use your additional treatment twice within a short period of time (e.g. 3 months).

Living Well with COPD

Fig. 89.8: Example of an action plan (*Source:* www.copdguidelines.ca)

Intensity and Duration of a Program

Intensity can refer to the intensity of the exercise prescription or the number of sessions per week. A minimum of three supervised sessions per week for six weeks are recommended, but due to recognized financial and time constraints, two supervised sessions with at least one other home session is acceptable. Additional home training alongside the supervised sessions should be commenced from the outset. There is ongoing debate about the optimum length of a program. Even very short programs (four weeks) can significantly improve exercise performance and the health-related quality of life, but longer programs (>12 weeks) may help sustain benefits. A minimum length of six weeks is recommended for the supervised program. As with many approaches to chronic conditions, the initial improvements will diminish in time in the absence of good adherence to the program guidelines.[9]

Maintenance

Follow-up and maintenance are required to sustain the benefits of pulmonary rehabilitation in keeping with the principles of long-term chronic disease management. A close relationship between primary and specialist care is also important as the majority of patients with COPD will be managed by their primary care physician or nurse practitioner.

As adherence to the exercise protocol decreases, the level of exercise achieved is often reduced. This is especially the case following a respiratory exacerbation.[27] There are many approaches to the frequency and location of the maintenance process, including whether it is necessary for this to be institutionally based or whether effective programs can be accessed through community centers. Repeat modified (short-term) programs result in similar short-term gains in exercise tolerance, but without an overall long-term benefit.[28]

Maintenance programs are modest in their effects[29] in part because they rely on behavioral changes to impact on lifestyle. In many health care systems cost is an obstacle, which makes any out of hospital solutions more attractive. Nevertheless, patients do discontinue pulmonary rehabilitation for a variety of social, motivational or medical reasons, including an acute exacerbation of COPD and intercurrent illnesses. Prediction of adherence is difficult, but it is likely that those who benefited little from the program will not subsequently maintain their exercise habits. Rolling programs have the advantage over fixed entry programs in that patients may enter or reenter at any time.

Oxygen

Supplemental oxygen during exercise may be required for safety reasons in those who exhibit profound desaturation. Under laboratory and field exercise conditions, oxygen can improve exercise performance by reducing the ventilatory requirements. However, the effects of training with supplemental oxygen have been variable[30,31] (Fig. 89.9). Carrying the weight of the

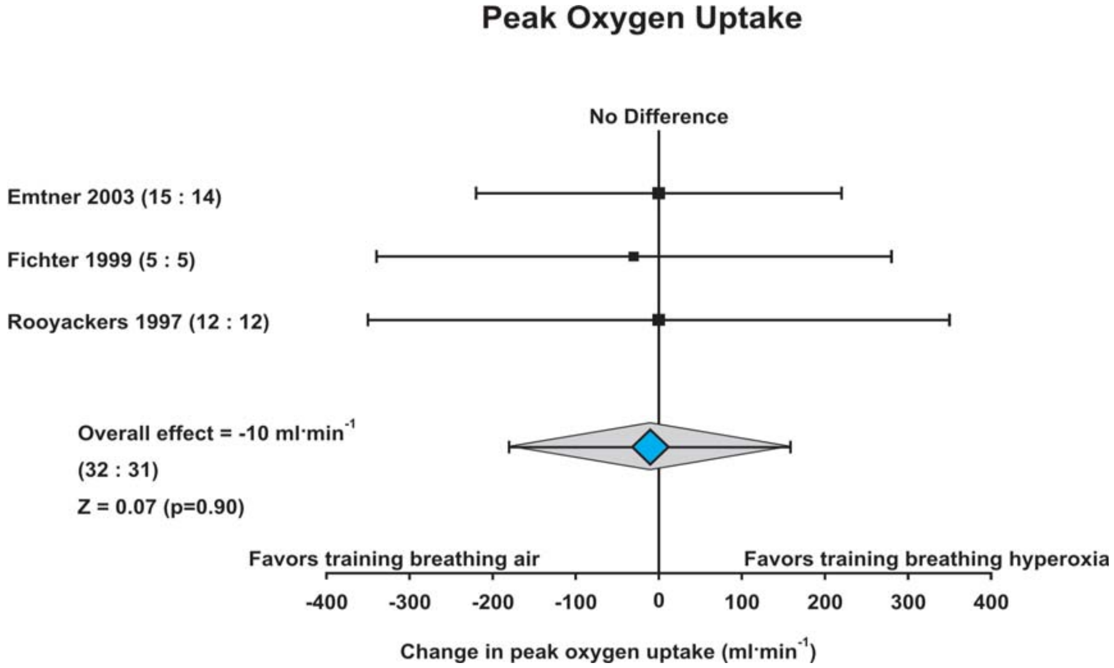

Fig. 89.9: Effect of training with supplemental oxygen

Note: The three studies included do not show evidence of change in peak oxygen uptake.[25,26]

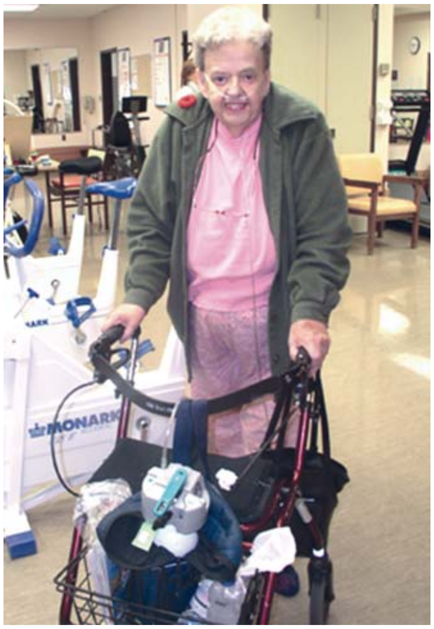

Fig. 89.10: Patient with rollator and oxygen

cylinder may negate any additional benefits. Although liquid oxygen is lighter to carry, it is expensive and not widely available.

Mobility Aids

Although walking sticks can improve balance and posture, rollators (Fig. 89.10) provide more stable support, improve balance and enable the user to sit comfortably on the seat provided. Rollators have been shown to improve walking distance especially among the more limited patients—unassisted 6MWD < 375 m.[32] These benefits are sustained if the patients continue to use the rollator at home.[33] Rollators also have the advantage of being able to carry oxygen or other small items, such as groceries.

The Rehabilitation Team

The multidisciplinary team should encompass the skills of respiratory physiotherapists, occupational therapists, nurses, assistants and physicians. It is often not possible to have the complete range of disciplines in person, but the skill set should be available. Team members should all have basic and intermediate life support skills and at least one member in the exercise sessions should have advanced life support skills. A minimum of one professional to eight patients is recommended. Experienced patients are a useful addition to the team, usually on a voluntary basis, and can provide further support to the patient group.

Quality Assurance and Audit

Programs should set up a regular audit to ensure that the results are in keeping with acceptable standards. Group aggregate data on walking distance and health status are frequently used. Feedback from patients can be collected by anonymous satisfaction questionnaire and data on compliance and dropout rates should also be recorded.

Setting

Pulmonary rehabilitation programs have been hospital based for stable disease both as in-patient and out-patient settings. There are limitations with this approach namely transport and accessibility. As in most countries, the provision of PR does not reach the demand, and community and home-based programs are sometimes available.[34,35] These alternate settings may be advantageous for patients still at work or wishing to avoid the difficulties of travel to a central site.

Exacerbations

Exacerbations are the real enemy of PR as all the components that improve with PR—dyspnea, exercise tolerance, muscle strength and health-related quality of life are all reduced following an acute exacerbation.[27,36,37] Many patients do not reach their preexacerbation level of functioning and clinical practice is of repeat referral for a shorter (booster) program. Currently most programs include patients with stable disease. There is some evidence that undergoing PR immediately post exacerbation is beneficial and not associated with adverse effects.[38] Targeting exercise therapy immediately post-exacerbation has a strong rationale, but whether morbidity can be improved in the long term needs to be investigated.

Performance Enhancement

Several approaches to enhancement have been evaluated. Calorie supplementation appears to help normal weight patients, but not those with cachexia.[39] Creatine supplementation has not been demonstrated to impact on exercise performance.[40] Anabolic agents are not currently recommended. Patients should be optimally pharmacologically managed prior to entry into PR and the addition of a long-acting anticholinergic has been shown to improve PR compared to placebo.[41]

Training Adjuncts or Strategies

These experimental strategies are included out of interest and to reflect the exciting ways in which exercise

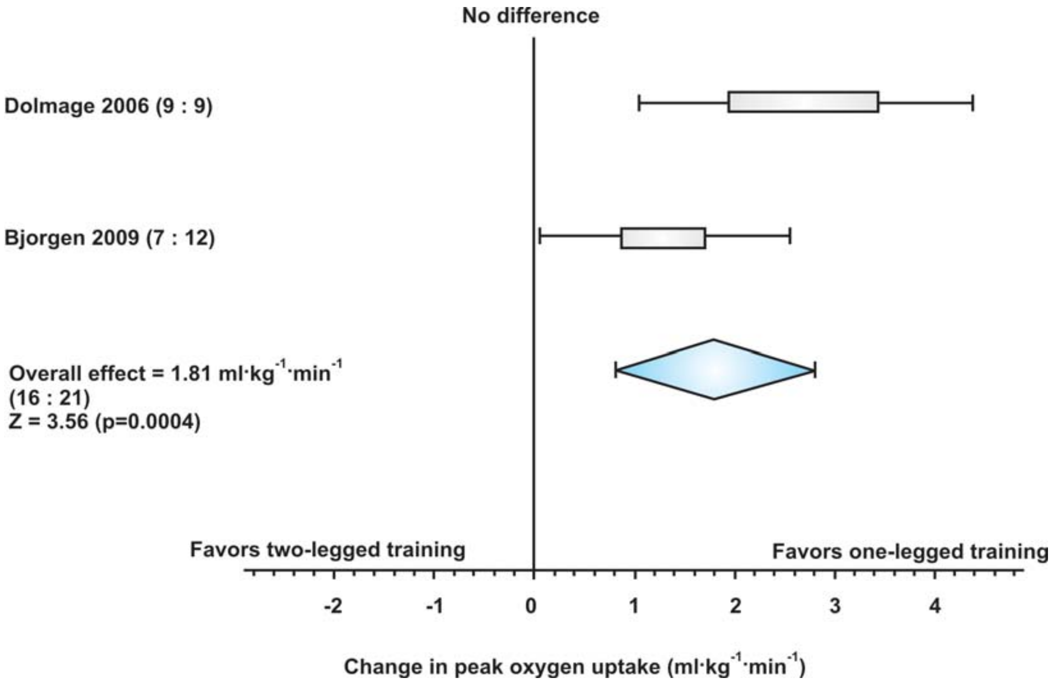

Fig. 89.11: Effect of one-legged training on peak oxygen uptake
Note: Improvement in peak oxygen uptake favors one-legged training.[41]

rehabilitation is challenging health care professionals to be creative. As ventilatory limitation is a major barrier to exercise training, the use of proportional assist ventilation (noninvasive ventilation), by means of a tight fitting mask, will improve endurance under laboratory conditions.[42] The use of a helium-hyperoxic mixture improves endurance time and enables a faster progression of training intensity, resulting in greater improvements in the health-related quality of life.[43] As helium is less dense, turbulence is reduced and laminar flow improved thereby reducing the work of breathing.

An approach that reduces the ventilatory load by limiting the muscle mass being exercised has generated considerable interest.[44] The reduced muscle mass reduces the amount of lactic acid. As the latter is buffered to release carbon dioxide, this reduction enables a lower ventilatory drive and therefore increases endurance. A training study has demonstrated that this is one of the few approaches to exercise training in COPD that will improve the peak oxygen consumption[45] (Fig. 89.11).

FUTURE WORK

Although much is known about the efficacy of short-term pulmonary rehabilitation, health care strategies are needed to ensure adequate access for the large population who stand to benefit from it. Pulmonary rehabilitation skills workshops especially when augmented by distance learning can assist with the dissemination of information required to develop small local programs. A clearer understanding of adherence requires an understanding of self-efficacy, behavioral adaptations and other determinant factors. Maintenance programs are necessary for comprehensive long-term management of chronic respiratory diseases, just as they are for nonrespiratory conditions. The frequency, content and duration of maintenance programs need to be better defined. Frequent exacerbations are likely to remain a large health care burden for patients with COPD and particular attention should be given to integrating exercise therapy early in the recovery period.

Pulmonary rehabilitation is an exciting field that has accomplished much over the last 25 years. Its growth and acceptance as mainstream management opens the way for further innovations.

Upper and Central Airway Obstruction

VR Pattabhi Raman

INTRODUCTION

Upper Airway Obstruction (UAO) can be classified as acute and chronic, the causes for both are quite different. Chronic UAO poses a diagnostic dilemma, and is frequently misdiagnosed and managed as bronchial asthma. On the other hand, acute UAO poses a therapeutic challenge and is best managed in a well equipped setting that has physicians trained in difficult airway management.

Anatomical Considerations

Upper airways obstruction is defined as the obstruction of the airways at or proximal to carina, including the nose, mouth, pharynx and larynx.[1] The problems relevant to these areas are usually dealt by the otorhinolaryngologists, therefore, readers interested in details are advised to refer to otorhinolaryngology textbooks. Also, obstructive sleep apnea, an important disorder causing upper airway obstruction is dealt separately in this textbook. This chapter essentially focuses on disorders that cause obstruction between the vocal cords and the carina. Tracheal obstruction at the level of thoracic inlet, including in the vocal cords and the cervical portion of trachea is called extrathoracic UAO whereas the obstruction in the thoracic portion of trachea till the carina is called intrathoracic UAO. This distinction is helpful as the changes in the airway dynamics that happen during respiratory cycle are different in the two segments. The intrathoracic segment of trachea increases in dimension during inspiration and decreases during expiration whereas it is the opposite in the cervical trachea and the airways above. The pressure that affects the caliber of upper airways in the extrathoracic region is atmospheric pressure (Fig. 90.1) and the intrathoracic pressure is the pleural pressure.[2] It is therefore, easy to imagine how narrowed (extrathoracic) upper airways cause snoring, which is typically associated with inspiratory collapse of the airways.

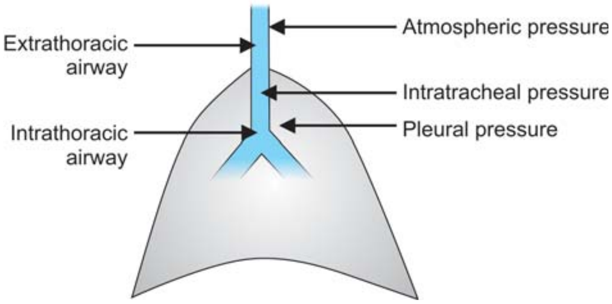

Fig. 90.1: Pressure affecting upper airways (Modified from JC Acres, MH Kryger. Clinical significance of pulmonary function tests: upper airway obstruction. Chest. 1981; 80:207-11)

Physiological Considerations

The classification of UAO on the basis of the anatomical landmark, i.e. the thoracic inlet has also got physiological significance and helps in the understanding of the differences that one sees when one assesses the flow-volume loops of extrathoracic and intrathoracic obstruction. Also, the nature of obstruction, whether it is stiff or pliable, determines whether there will be changes in severity in relation to changes in the transmural pressure. A stiff lesion as in some cases of postintubation tracheal stenosis, does not allow dynamic differences in the diameter of the stenosis and in the airflow between inspiration and expiration.[2] This is called fixed airway obstruction. In cases of bilateral abductor palsy of vocal cords, there are differences in the caliber and the airflow during the respiratory cycle. Because of the extrathoracic nature of the obstruction, inspiration worsens and expiration lessens the obstruction. This is an example of variable airway obstruction. Based on these parameters, UAO can be divided into fixed obstruction, variable extrathoracic obstruction and variable intrathoracic obstruction.

Clinical Features

Acute airway obstruction usually has a dramatic presentation and seldom poses a diagnostic challenge. It usually presents as severe breathlessness and agitation. Stridor is the usual diagnostic sign. Stridor is frequently audible unaided and stethoscope is seldom required.

Chronic obstruction is frequently misdiagnosed and managed as asthma and/or Chronic Obstructive Pulmonary Disease (COPD) for a variable period of time before the recognition of upper airway problem. The patient may also present very late in the course of the disease. The presence of stridor in UAO means a fairly severe narrowing. It has been known for almost four decades that tracheal lumen of less than 8 mm produces symptoms after exercise[3] and of less than 5 mm produces stridor.[4] High index of suspicion is usually required in chronic UAO. Diligent history-taking including the history of intubation and of thyroid surgery could serve as a clue. Many cases of chronic UAO have periods of worsening, which get better with antibiotics and steroids, further delaying the diagnosis. Certain features, such as hemoptysis, and relative refractoriness to asthma treatment should alert the physicians about the possibility of UAO and the need for further investigations.

Diagnosis

Radiology

Plain X-ray is seldom useful. It may show obvious mediastinal lymphadenopathy or sometimes a tracheal tumor with extramural extension. At times, the penetrated film may show the site of obstruction.

Computed Tomography (CT) is very valuable to diagnose airway obstruction. In particular, the reconstructed images (Fig. 90.2) provide relevant details about the site, the extent and the nature of obstruction. The diameter at the most narrow portion and the length of the stenosis are critical details that are required to plan treatment. The present generation multiplanar CT provides this information in a very short time. Some patients with very severe stenosis may not be able to lie down flat and hold their breath for the study. Magnetic Resonance Imaging (MRI) is not very commonly sought. It may give valuable information by its superior contrast resolution.

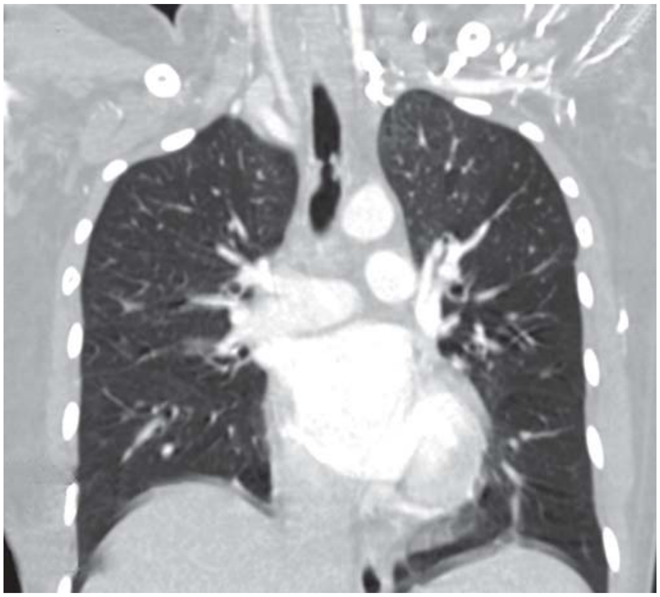

Fig. 90.2: Reconstructed CT image of a patient with tracheal stenosis

Spirometry

In normal subjects, during a forced expiration from Total Lung Capacity (TLC), the maximum airflow is achieved during the first 25% of the Vital Capacity (VC), which is directly dependant on effort and inversely to the resistance. In the remaining 75%, the flow is limited in such a way that an increase in effort (and the associated increase of pleural pressure) does not result in increased flows.[3] With UAO, flow at higher lung volume may be limited by obstruction. UAO causes more pronounced decrease in Peak Expiratory Flow (PEF) than in the FEV_1.[5] Therefore, an increased ratio of FEV_1 (ml) divided by PEF (L/ml) can alert the clinician to the need for an inspiratory and expiratory flow-volume loop.[6] This ratio is called as Empey's Index, the value of more than eight suggest the presence of central or upper airway obstruction.[7] Poor initial effort by the patient can also increase the index. Hence, it is very important that the patient's inspiratory and expiratory efforts are maximal

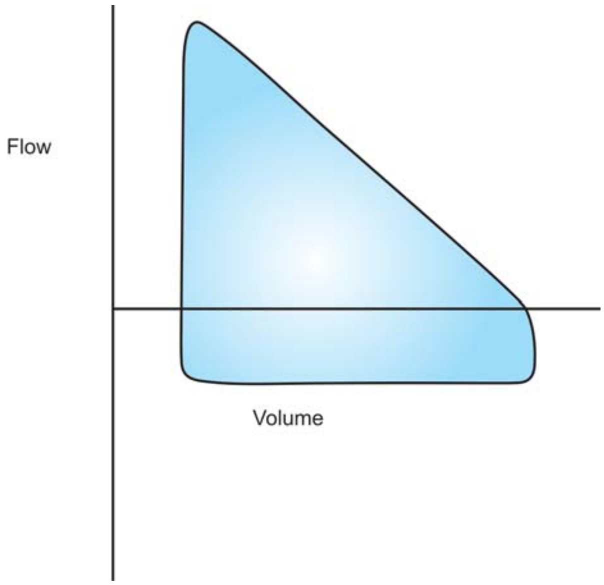

Fig. 90.3A: Variable extrathoracic obstruction

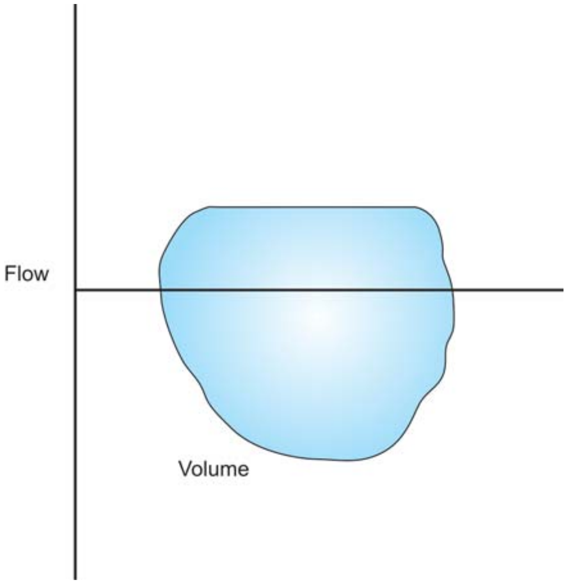

Fig. 90.3B: Variable intrathoracic obstruction

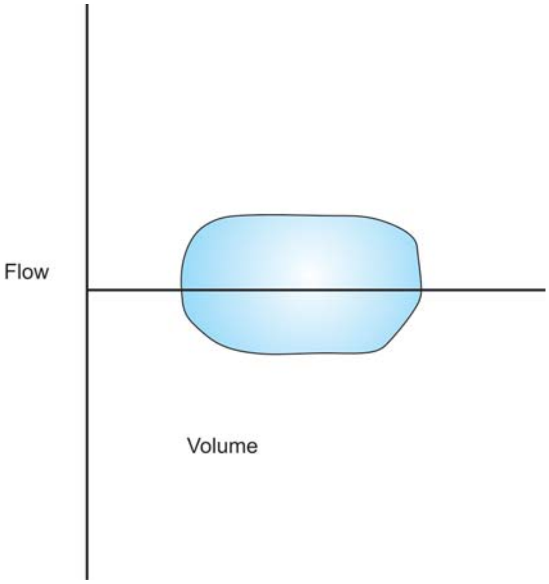

Fig. 90.3C: Fixed airway obstruction

Figs 90.3A to C: Flow-volume loop in UAO (Adapted from Miller and Hyatt. Obstructing lesions of the larynx and trachea: clinical and physiologic characteristics. Mayo Clin Proc. 1969; 44:145-61)

and the technician should confirm this in the quality notes.[5]

Flow-Volume Loop

Miller and Hyatt[8] did elegant experiments by simulating UAO in normal subjects and found that flow-volume loop would be particularly useful in diagnosing and categorizing UAO.[5] When patient's effort is good, the pattern of repeatable plateau of forced inspiratory flow, with a preserved expiratory flow loop indicates variable extrathoracic UAO (Fig. 90.3A), while the pattern of repeatable plateau of forced expiratory flow along with a preserved inspiratory loop indicates variable intrathoracic UAO (Fig. 90.3B).[5] The pattern of repeatable plateau at a similar flow in both forced inspiratory and expiratory flows suggests a fixed UAO (Fig. 90.3C).[5] The absence of classic patterns does not rule out UAO. The presence of specific UAO patterns would also warrant confirmation of the presence of UAO, hence bronchoscopy is required as the next important step.

Bronchoscopy

Bronchoscopy, which provides the most useful information in UAO, is the procedure of choice. It is useful to have an idea about the lesion with a CT done before bronchoscopy so that planning could be better. The cause of the anatomical obstruction can be diagnosed in the case of an intramural pathology like a tumor. Care however has to be taken while passing a flexible bronchoscope through a very narrow lumen, since even a minor hemorrhage can become catastrophic by causing critical airway narrowing. It is wise to employ rigid bronchoscopy in such a case of severe obstruction. During rigid bronchoscopy, ventilation can be done during the procedure and therefore, oxygenation is easy. Moreover, the larger bore of the rigid barrel allows the passage of instruments simultaneously, and procedures like biopsy can be safely done. Also, the barrel of the bronchoscope could be used to tamponade bleeding points and to mechanically dilate the tracheal stenosis. Another significant advantage of rigid bronchoscopy is the deployment of silicone stents, making it the investigation of choice in severe upper airway obstruction.

In cases of extrinsic obstruction, bronchoscopy could be valuable in assessing the mucosa, if there is a transmural invasion. It also helps in assessing the extent of involvement to guide a definitive therapy. In the cases of functional obstruction, such as in tracheomalacia, bronchoscopy is mandatory. Here, flexible bronchoscopy scores over the rigid bronchoscopy to identify abnormal airway dynamics during respiration would mandate an awake and cooperative patient on the table, which is not possible in an anesthetized patient undergoing rigid bronchoscopy.

ACUTE UAO

Foreign Body

Typically seen in children aged between 2 and 4 years, aspiration of foreign bodies can be also seen in older children and the elderly individuals. In the elderly patients, it commonly occurs in the presence of comorbidities with depressed consciousness and poor swallowing reflex.[9] In pediatric population, choking is the most common symptom followed by a protracted cough.[10] There is a male preponderance and more often when there is an elderly sibling. No predilection between right and left bronchial tree is seen, at that age the bronchial division makes a similar angle on both the sides. History may not be forthcoming in all cases and high index of suspicion is required.[11] Radiography is useful only in the case of radiopaque foreign bodies or when there is expiratory hyperinflation.[10] Normal chest X-ray does not exclude foreign body aspiration. Early intervention is important especially when vegetable matter like groundnut or bean is aspirated since granulation happens rather rapidly and at times so profusely that it may not be visible in bronchoscopy.[12] Also, delayed removal may not result in complete healing of the granulation tissue. Groundnut is probably the most common foreign body among children in India.[11] Though rigid bronchoscopy is considered the gold standard for the retrieval of an aspirated foreign body, there is a definite role for flexible pediatric bronchoscopes for both diagnosis and retrieval of pediatric foreign bodies.[13-15]

Acute Laryngeal Edema

Acute laryngeal edema may happen following anaphylactic reactions causing life-threatening angioedema, prototype being the penicillin allergy or Nonsteroidal Anti-inflammatory Drugs (NSAID) allergy in aspirin-sensitive asthma. The deterioration is rapid and early intervention is crucial. Parenteral administration of adrenaline can be life saving.

This has to be distinguished from a rare autosomal dominant condition called hereditary angioedema. This condition happens secondary to deficiency of C1 inhibitor enzyme due to mutations of its gene.[16] Localized swelling that is self limiting, can happen at any site of the body including the skin, genitalia, and the gastrointestinal tract. The angioedema is life threatening when it happens in the larynx, especially if untreated.[17] The attacks are not precipitated by allergy, but by trauma and stress.[17] The age of presentation is variable. Prophylaxis is useful if started early (with tranexamic acid) or attenuated with androgens like danazol.[18] In patients refractory to prophylaxis of danazol, pasteurized plasma-derived C1 inhibitor (pC1-INH) concentrate has been found to be useful in reducing the recurrence.[19] In acute attacks, pC1-INH concentrate (intravenous dose of 20 U/kg) and newer drugs like Icatibant, bradykinin receptor-2 antagonist (30 mg subcutaneous injection) have been shown to provide rapid relief.[20,21]

Another important cause for nonallergic laryngeal edema is the administration of Angiotensin-converting Enzyme Inhibitors (ACEI) which, like hereditary angioedema is not associated with itching or urticaria.

Prompt recognition and stopping the drug will stop the recurrence. Recent studies have described the increased incidence of angioedema in renal transplant recipients receiving a combination of ACEIs and mTOR inhibitors.[22]

Infection

Infection as a cause of acute UAO typically occurs in children. This may include infections, such as acute epiglottitis caused by either *Haemophilus influenzae* or beta-hemolytic streptococci and Ludwig's angina characterized by a rapidly progressing cellulitis involving submandibular space. The treatment involves rapid airway stabilization, antibiotics and surgical drainage of the pus.

Viral croup often caused by parainfluenza virus, is managed by nebulized adrenaline and parenteral corticosteroids. Bacterial tracheitis is usually caused by *Staphylococcus aureus* infection. Bronchoscopic appearance shows the presence of erythema, edema, thick secretions and at times, plaques in the trachea.

CHRONIC UAO

Vocal Cord Dysfunction

This is a syndrome in which the vocal cords adduct during inspiration producing upper airway obstruction like features. Patients are usually females in the age group of 20 to 40 years.[23-25] It masquerades the diagnosis of refractory asthma with multiple attacks, is usually managed as asthma. In an Indian study that evaluated difficult to control asthma, vocal cord dysfunction was seen in about 23.5%, and also frequently found to coexist with asthma.[26] A recent review described exercise, psychological stress, irritants, rhinosinusitis, gastroesophageal reflux disease as the usual triggers.[27]

The "wheeze" typically appears at lower lung volumes since the obstruction happens during the inspiration and for the same reason, the chest X-ray does not show hyperinflation. Spirometry done during the episode may show the classical loop of extrathoracic UAO. Flexible laryngoscopy is considered the gold standard for diagnosis, especially when done during the episode. The classical description during the inspiration consists of adduction of the vocal cords, with a small diamond-shaped chink in the posterior region of the vocal cords. Reassurance and breathing exercises may reduce the intensity during the acute episode and interestingly, rapid shallow breathing (like panting) has been found to be useful.[28] Speech therapy, psychological counseling and avoidance of triggers would help in long-term management.

Tracheobronchomalacia

Tracheomalacia (TM) refers to the weakness of tracheal walls, frequently due to reduction and/or atrophy of the longitudinal elastic fibers of the pars membrane; or cartilage integrity, such that the airway is softer and more susceptible to collapse.[29] Tracheomalacia may be localized or diffuse and usually affects intrathoracic portion of trachea. If main bronchi are also involved, it is called tracheobronchomalacia (TBM).

Pediatric TM

TM is the most common congenital abnormality of trachea.[30] There is a strong association with prematurity,[31] mucopolysaccharidosis and tracheoesophageal fistula,[29] and some congenital heart diseases.[29] There is a male preponderance. Acquired causes include long-standing tracheostomy, and pressure from vascular slings. Congenital TM is usually self limiting and the children outgrow the disease by the age of 2–3 years. Severe cases are managed by the use of Continuous Positive Airway Pressure (CPAP), or by surgical procedures like aortopexy.[32]

Adult TM and TBM

There is an increased awareness in recognizing and implicating TM as an important cause for pulmonary symptoms. This can be attributed to the advances in CT technology and virtual bronchoscopy, increasing availability of bronchoscopes and of better therapeutic options.

TM in adults is predominantly seen in the middle-aged male individuals who are also smokers. Adult cases most commonly happen following the trauma, including after intubation, tracheostomy, external chest trauma, and after lung transplantation. Emphysema, chronic bronchitis, chronic inflammation like relapsing polychondritis, and chronic extrinsic compression of the trachea are the other important reasons.

Acquired tracheomalacia is commonly seen in association with long-term intubation and tracheostomy. It is usually a short segment stenosis. A comprehensive in depth review on tracheomalacia describes that the length of malacic segment secondary to postintubation in usually less than 3 cm.[29] More than 50% decrease in airway caliber occurring during expiration is diagnostic of TM. Three types are described:[29]

1. Saber-sheath type (Ω)—lateral wall narrowing
2. Scabbard type (◠)—AP narrowing-crecentic type
3. Circumferential type (O)—all round narrowing.

The TM secondary to COPD is usually diffuse, and also, difficult to treat. The patient presents with symptoms such as cough, dyspnea and wheeze. Dynamic CT, which is noninvasive, is useful for diagnosis. The multidetector CT technology shows very good promise.[33]

Symptomatic cases need to be treated depending on the etiology. Focal TM in postintubation or post-traumatic cases should be respected, if possible. Alternatively, it can be managed with tracheostomy, if the segment can be bye-passed. The advantages of tracheostomy in such a situation is that the tube acts like a stent. Long flange tracheostomy tubes are available for the purpose. The tracheostomy can also be an interface for CPAP application. However, tracheostomy can also predispose to tracheomalacia of a different segment of trachea.

In TM secondary to COPD, the optimization of medications for COPD can help reduce symptoms. Severe cases can be managed with silicone stents. However, it is not effective in all patients and there is a high chance of migration of these stents. Metallic stents should be avoided because of the difficulty of removal and replacement. Different surgical means have been tried. Strengthening the posterior membranous portion using various prostheses like crystalline polypropylene mesh, has been tried with variable success.[34]

Polychondritis

Relapsing Polychondritis (RP) is a rare and interesting disease. It is a multisystem disorder with unknown etiology, characterized by recurrent progressive inflammation and degeneration of the cartilage and the connective tissue.[34] RP affects people between 2 and 80 years of age and has equal gender distribution. The airway complications in about 50% of the cases, are seen more often in females than in males, and carry a poorer prognosis.[35-37]

Diagnostic Criteria

Criteria for the diagnosis of RP were described initially by McAdam and associates.[36]

Presence of three or more of the following criteria are employed for diagnosis:

1. Chondritis of larynx, trachea or bronchitis
2. Chondritis of nasal cartilages
3. Chondritis of both auricles
4. Audiovestibular damage (Sensory-neural hearing loss, tinnitus and vertigo)
5. Ocular inflammation
6. Nonerosive seronegative inflammatory polyarthritis.

The criteria were modified by Dammantt and Levine[38] to include histological features and therapeutic responses. The modified criteria include the presence of any one of the following combinations:

1. Three or more of McAdam's criteria (No tissue confirmation needed).
2. One or more of McAdam's criteria with positive histological confirmation by biopsy of the cartilage.
3. Involvement of two or more separate anatomic locations with response to steroids and/or dapsone.

Clinical Features

Clinical features depend on the cartilage that is involved. It is important to understand that apart from cartilaginous structure of the external ear, nose, peripheral joints, larynx and tracheo bronchial tree, other proteoglycan-rich structures can become involved, including the heart, blood vessels and inner ear.[39]

Airway Complications

The prevalence of symptomatic airway involvement was reported in 21% with female preponderance in about 70% patients.[37] The usual symptoms were progressive dyspnea, cough, stridor, hoarseness, chest discomfort and features of respiratory failure. The presence of airway symptoms were the first manifestation of RP is about 50% of patients with airway manifestation. Airway obstruction in RP can occur due to any of the following:[40]

1. Acute airway inflammatory swelling and airway narrowing.
2. Tracheobronchomalacia—due to progressive destructions of the cartilage.
3. Formation of fibrous tissue and cicatricial contraction at a later stage.

Investigations

Pulmonary function tests show mixed pattern.[37] Dynamic CT scan and bronchoscopy (Fig. 90.4) provide the vital details in RP regarding the extent and severity of the airway problem. Typical CT findings include the presence of diffuse tracheobronchial stenosis (better seen with reconstructed CT images), dynamic expiratory collapse or anterior bronchial wall thickening with posterior sparing. Typical bronchoscopic findings include supraglottic and false vocal cord edema, subglottic stenosis or tracheomalacia.[37]

Treatment

Many medications, such as the steroids, mycophenolate mofetil, methotrexate and dapsone have been tried, but the response to treatment is variable. Newer biological agents like rituximab, etanercept and abatacept show

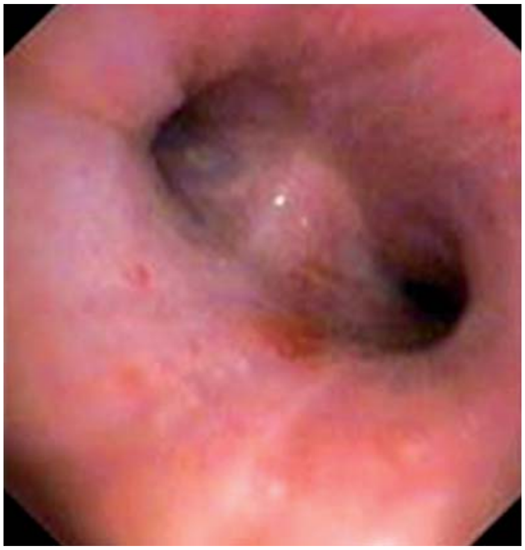

Fig. 90.4: Relapsing polychondritis. Fifty-year-old lady: Biopsy proven relapsing polychondritis. Note the absence of cartilage prominence at the level of distal trachea

some promise. Bronchoscopic techniques, such as balloon dilatation, and tracheobronchial stenting used alone or in combination might give some respite from symptoms for patients with airway complications.[41] Interventional procedures provide a good short term relief. However long-term outcome is quite variable.

Tracheopathia Osteochondroplastica (TPO)

It is a rare, slowly progressive disorder of unknown etiology. Endoluminal projections of bony and cartilaginous nodules arise from the submucosa of the trachea. There appears to be a male predominance and usually presents in the sixth or seventh decades of life.[42] The nodules characteristically spare the posterior membrane (Fig. 90.5), but may be present in the proximal, main bronchi also. The presentation is usually with chronic cough, dyspnea in advanced cases and minimal hemoptysis due to the ulceration of the overlying mucosa.[43] Diagnosis is based on typical bronchoscopic appearances, biopsy is not generally needed .There is no definitive treatment. Severe obstruction may warrant therapeutic interventions.

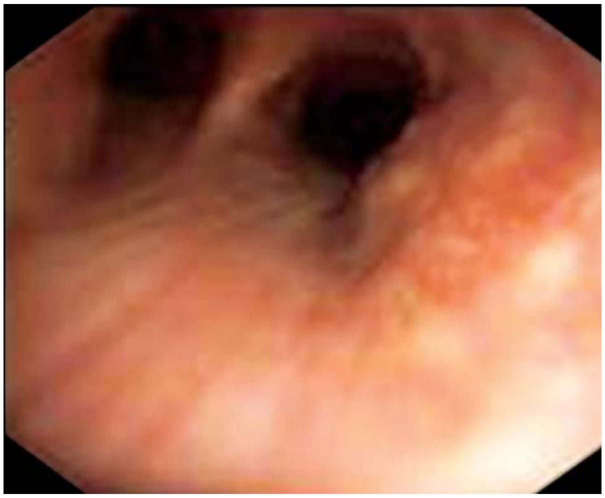

Fig. 90.5: Case of tracheopathia osteochondroplastica. Note the nodules seen only on the cartilaginous portion of trachea and sparing of membranous portion

Tracheobronchial Amyloidosis (TBA)

TBA is very rare, characterized by endoluminal accumulation of abnormal proteins in the form of fibrils, which cause obstructive symptoms. In a retrospective review of 17 biopsy proven TBA over a 26-year period, Capizzi and colleagues from Mayo Clinic described dyspnea, cough, hemoptysis and hoarseness as presenting symptoms.[44] Diagnosis is made by bronchoscopy and biopsy with specific congo red staining. Response to medications like steroids and melphalan are suboptimal, severe obstruction warrant debulking.

Tuberculosis (TB)

Endobronchial TB is not an uncommon problem in the developing world. The true incidence in patients with sputum-positive pulmonary tuberculosis is difficult to estimate because bronchoscopy is usually avoided. Endobronchial tuberculosis is seen more commonly in females, perhaps because they tend to retain the infected secretions in the bronchial tree and avoid expectoration. It is also more common in the left than the right side bronchi probably because the left main bronchus is narrow and lengthy and hence the infected sputum may remain in contact with the bronchi for a longer time. Since the infected sputum cannot remain in the trachea, endotracheal tuberculosis (Fig. 90.6) is very rare, but presents a formidable challenge to the treating clinician. The disease is quite refractory to chemotherapy alone. Chung and Lee classified endobronchial TB into seven types based on the bronchoscopic appearance: [45,46]

- Active caseating
- Edematous-hyperemic
- Fibrostenotic
- Tumorous
- Granular
- Ulcerative and
- Nonspecific bronchitic

Once the lesion becomes fibrostenotic, which is a final path for all the types, it becomes resistant to therapy.

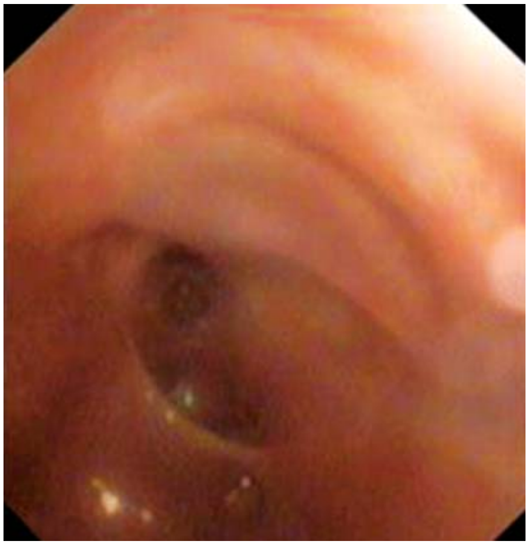

Fig. 90.6: 21-year-old lady known case of sputum-positive pulmonary kochs developed severe respiratory distress despite therapy. She had endotracheal fibrostenosis in distal trachea, which was dilated

Hence, early identification by bronchoscopy is encouraged in a suspected patient. Suspicion arises if a patient with TB develops wheeze or breathlessness. Surgery is ideal if the involved segment is small. If the disease is extensive, balloon dilatation or thermal desobstruction followed by silicone stenting can be tried.[47]

Sarcoidosis

As in tuberculosis, an airway abnormality in sarcoidosis is often overlooked. Endobronchial involvement is usually seen in the elderly age groups, smokers during advanced stages of parenchymal involvement and with thickening of bronchovascular bundles on high resolution computed tomography. It carries a relatively poorer prognosis.[48] Flow limitation is seen in about 9% of patients with sarcoidosis.[48] Sarcoidosis can affect every part of upper airway. Sarcoid involvement of the supraglottic airways, larynx, and central and peripheral airways is also described.[49] Obstructive sleep apnea syndrome is seen more often in patients with sarcoidosis, especially lupus pernio.[50]

Tracheal obstruction secondary to sarcoidosis is very rare. After an early case in 1981, not many reports of tracheal obstruction have appeared.[51] The classic endobronchial sarcoidosis is characterized by mucosal islands of waxy yellow mucosal nodules, measuring 2 to 4 mm in diameter.[49] The nodules are sparse in the trachea, but abundant in the main, lobar and segmental bronchi. Other changes are mucosal erythema, granular mucosa, cobblestone mucosa, mucosal plaques, bronchial stenosis, airway distortion due to cicatricial changes in parenchyma, bronchiectasis, extrinsic compression due to mediastinal lymphadenopathy or airway hyper responsiveness.[49]

Tracheal Stenosis

Tracheal stenosis is an important cause of upper airway obstruction. It may happen secondary to trauma to trachea, following prolonged intubation, i.e. post-intubation tracheal stenosis (PITS) and after tracheostomy, i.e. post-tracheostomy tracheal stenosis (PTTS). Idiopathic stenosis is rare.

Mechanical ventilation has made a great difference in the outcome of many sick patients with respiratory failure, but the use of endotracheal tube have resulted in a group of diseases that have become more common than before. Despite the use of low pressure cuffs, which have reduced the incidence of tracheal stenosis significantly, the incidence of PITS and PTTS is high, i.e. 0.6 to 21%.[52-57] It is seen predominantly in females, presumably because of smaller tracheal lumen and hence, prone to injury.[52,53,58,59]

Classification

Brichet and colleagues[60] classified the postintubation tracheal stenosis based on bronchoscopic appearance into three types:

1. *Web-like membranous stenosis:* A short segment (<1 cm) concentric stenosis with no cartilage damage (Fig. 90.7A).
2. *Pseudoglottic stenosis:* "A" shaped stenosis secondary to lateral impacted fracture of cartilage in patients following tracheostomy. Since the stenosis resembles a vocal cord, it is called pseudoglottic stenosis (Fig. 90.7B).
3. *Complex stenosis:* It includes all other varieties, including extensive (>1 cm), circumferential hourglass-like contraction scarring or malacia. Basically, there is a cartilage damage along with the narrow lumen (Figs 90.7C and D).

The membranous and complex types are most common.

Pathogenesis

Usage of high cuff pressure in an intubated patient predisposes to mucosal ischemia, which also worsens in the presence of hypotension when the capillary pressure is lower. Pressure necrosis and chondritis result, which lead to either the development of cicatricial tissue and

(*Courtesy:* Dr Ravindra Mehta, Bengaluru)

membranous type of stenosis or to the cartilage damage and weakening causing a complex stenosis.

Stenosis usually develops at the site of the cuff, though the distal end of the tube, because of the repetitive injury, may also be involved. In post-tracheostomy stenosis, stoma of the tracheostomy is an additional site for stenosis. Stenosis caused by percutaneous tracheostomy occurs earlier and subglottic in nature when compared to that caused by surgical tracheostomy.[56]

Management

Management of tracheal stenosis depends on the type of stenosis, presence of comorbidities, functional status of the patient, and the length of the stenosis. While surgical tracheal sleeve resection is a permanent solution considered the gold standard, it carries 3% mortality in trained hands. A multidisciplinary approach incorporating both surgical and bronchoscopic techniques is preferably employed.[60]

Bronchoscopic Management

Bronchoscopic management is sufficient in a majority of cases of membranous stenosis and can be very useful as either a stand-alone therapy or as a bridge to surgery in very sick patients. Bronchoscopy is used both for achieving and maintaining an effective lumen. Some of procedures to tackle membranous stenosis can be done with a flexible bronchoscope, but it is important that the bronchoscopist is trained in rigid bronchoscopy as well. Better ventilation, better control of secretions and of bleeding during the procedure and more importantly, the option of deploying silicone stents makes rigid bronchoscopy the procedure of choice.

The general recommendation by the FDA is to avoid metallic stents for such benign causes of tracheal obstruction.[61] Since the stent placement for benign lesions (PITS being the prototype) is usually temporary, it is customary to remove the stent and assess after 12 to 18 months of deployment to see the tracheal function effectively without the stent. Deploying metal stents is easy, can be done through flexible scope and can be done with little training, hence very popular. However, removal of stent after it is deployed is a messy affair. It cannot be removed in toto, needs trained physician with rigid bronchoscopy skills. Hence, a silicone stent is the standard choice for supporting stenosis secondary to cartilage weakness.

In membranous stenosis, stent is not required after dilatation since the cartilage is not involved, and the stability of airway is not affected. In complex stenosis, however, the underlying cartilage is damaged and collapsible. Therefore, despite achieving a good lumen by bronchoscopic means, it has to be followed by leaving a stent at the end of procedure.

Managing patients with tracheal stenosis is all about two important components: (i) to achieve an effective lumen, and (ii) to maintain the lumen:

i. *Achieving effective lumen:* Many techniques are described, which are broadly classified as mechanical or thermal. Dilatation using rigid bronchoscope-barrels of increasing diameters, dilators, balloon dilatation and making nicks in the membrane using rigid scissors are some of the techniques. Laser and electrocautery can be used to cut the membranes with Mercedes Benz incisions, which are mucosa sparing. They prove to be curative in about 65% cases when repeated up to three times.[62]
ii. *Maintaining the lumen:* For membranous stenosis, achieving an effective lumen would suffice. However, in complex stenosis, because of cartilaginous weakness, achieving effective lumen shall usually be followed by silicone stenting.

It is important to realize the importance of being gentle with the airways since the best approach to tracheal stenosis is to prevent its occurrence. Using appropriate cuff pressures and using noninvasive ventilation when indicated are important considerations. Newer endotracheal tubes that do not have cuffs and have ability to mould to the shape of the intratracheal airways have been tested in animals and show good promise in reducing tracheal injury.[63]

Idiopathic Tracheal Stenosis

Idiopathic tracheal stenosis is a rare condition. It is seen almost exclusively in females, involves the upper trachea, predominantly, the immediate subglottic portion.[64] Many causes have been proposed, it may represent some form of fibromatosis.[64] Immunohistochemical staining for estrogen receptors is usually positive. Gastroesophageal reflux disease is seen in about a third of cases. Usual treatment consists of dilatation, tracheostomy or if feasible, resection of the involved cartilage.

Extrinsic Compression

Extrinsic compression of trachea occurs from the enlargement of structures nearby such as the malignant lymph nodes, thyroid enlargement (both benign and malignant), esophageal tumors and occasionally vascular problems. Vascular problems may more often cause tracheomalacia secondary to a long-standing pressure effect than anatomical obstruction. In a patient with esophageal malignancy for whom surgery is not done due to any reason, stenting the esophagus is a popular intervention. However, in the presence of partial tracheal obstruction, stenting the esophagus may precipitate severe airway obstruction. In such a situation, trachea is stented first, followed by esophageal stenting (Fig. 90.8).

Both benign and malignant disorders of thyroid can cause UAO. Airway obstruction is an indication for surgery in both benign and malignant thyroid problems. Mechanisms of airway obstruction include extrinsic tracheal compression (e.g. benign intrathoracic or substernal goitre), tracheal invasion by a growth, vocal cord paralysis (e.g. recurrent nerve paralysis after

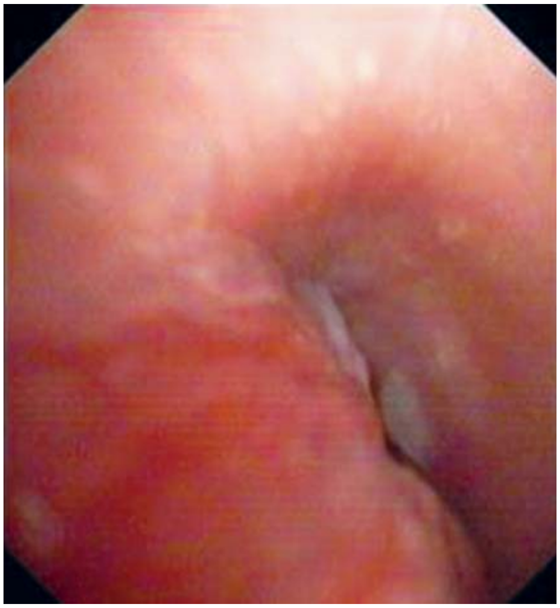

Fig. 90.8: A 60-year-old lady with esophageal malignancy causing near total occlusion at subglottic region

thyroidectomy), or a combination of the above (Fig. 90.9).[65] In a series of 30 patients with thyroid disorders causing UAO who were also not candidates for surgery due to various reasons, there is a great utility of rigid bronchoscopy and laser application in providing both immediate and long-term benefits.

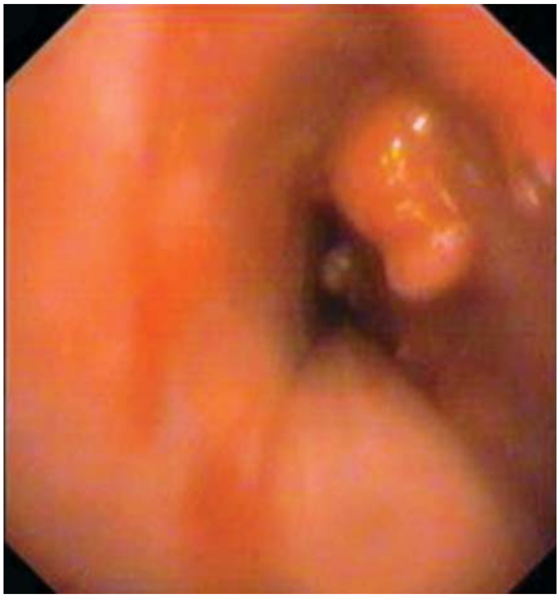

Fig. 90.9: Elderly lady with thyroid malignancy causing both extrinsic compression and tumor infiltration of upper trachea

Wegener's Granulomatosis

Upper Airways are commonly involved in Wegener's granulomatosis most of the times. Nasal and oral ulcerations, granulomatous inflammation, epistaxis, sinusitis and otitis, are common manifestations.[66,67] Usual features are ulceration of larynx and trachea. However, a rare but a significant airway problem is subglottis stenosis. This has been reported to develop during treatment with steroid and cyclophosphamide.[68] It is typically dealt by interventional techniques like laser application[68] or dilatation.[69] Recently, intralesional long-acting corticosteroids have found to be effective.[70]

Tumors

Primary tracheal tumors are very rare, seen in about 0.2 per 100,000 persons[71] of whom about 80% are malignant. Primary tracheal tumors can arise from the respiratory epithelium, salivary glands, and mesenchymal structures of the trachea.[72] Squamous and adenoid cystic carcinoma account for about two-thirds of tumors from trachea. The other malignant tumors are mucoepidermoid carcinoma, arising from the submucosal glands. Neuroendocrine neoplasm are seen more in bronchi than in trachea and include typical and atypical carcinoids, large cell neuroendocrine tumors and small cell carcinoma. The difference between the primary tracheal tumors and the bronchogenic malignancies is that the tracheal tumors have a better long-term prognosis and need more aggressive approach in providing good palliation or a cure.[73] Benign tumors of the trachea include tumors from surface epithelium like papilloma, papillomatosis, tumors from glands (like pleomorphic adenoma, mucous gland adenoma, myoepithelioma and oncocytoma) and tumors from mesenchymal structures (like fibroma, benign fibrous histiocytoma, hemangioma, paraganglioma (chemodectoma), hemangiopericytoma, glomus tumour, chondroma, lipoma, and leiomyoma granular cell tumors.[72]

Endotracheal metastases are much less common than endobronchial metastasis. Endobronchial metastasis commonly arise from renal, colon, or bronchogenic malignancy, melanoma and osteosarcoma. Presentation of metastases as UAO is very rare.

Other Causes

Bilateral vocal cord palsy can happen secondary to thyroid malignancy or thyroid surgery. Others include the neurological diseases or idiopathic causes. Cases of bilateral vocal cord palsy have been reported following nasogastric tube, systemic lupus erythematosus (SLE) and esophageal surgeries.[74-76] Other rare and diverse causes of UAO have been described as anecdotal case reports.[77-83]

THERAPEUTIC CONSIDERATIONS

As is true with many other conditions in medicine, treating the primary cause of the UAO is important. However it is also important to manage the obstruction. Obstruction can occur due to intrinsic pathology as in the case of tumors or tracheal stenosis, extrinsic compression as in compression from thyroid swelling or esophageal cancer. Functional obstruction without significant anatomic narrowing can happen secondary to tracheomalacia. In cases where surgery is feasible, especially in short segment complex stenosis or tracheal tumors, it should be offered. Several other interventional approaches provide a good quality of life in most of the conditions.

In the cases of intramural pathology, achieving a patent lumen is accomplished by techniques like rigid bronchoscopy, laser, electrocautery, and argon plasma coagulation, while airway stenting is necessary for extramural compression or tracheomalacia where maintaining lumen is the key issue. Silicone stents are preferred over metallic stents because the latter are difficult to remove after deployment. A recent study shows that most of the cases of UAO secondary to tracheal stenosis could be managed using flexible bronchoscopy, for balloon dilatation, laser application, stent placement and brachytherapy.[84] But rigid bronchoscopy is generally preferred because of a better control of airway, ventilation and for deployment of silicone stents.

Bronchiolar and Bullous Lung Diseases

Gyanendra Agrawal, Dheeraj Gupta

INTRODUCTION

In addition to Chronic Obstructive Pulmonary Disease (COPD), asthma and cystic fibrosis, the "obstructive pulmonary disorders" include an important group of diseases—small airway diseases. The first part of this chapter focuses on the clinical approach to bronchiolar disorders. It also includes discussion on the bullous lung disease, highlighting its key differentiating features with bullous emphysema, in the later part.

BRONCHIOLITIS

The term "small airways" refers to airways less than 3 mm in diameter.[1,2] This definition includes small bronchi, bronchioles and respiratory bronchioles. Bronchioles are small airways less than 2 mm in diameter without cartilage or submucosal glands. This includes terminal bronchioles, whose principal role is to conduct air to the respiratory bronchioles. The latter contain alveoli, which are the site of air conduction and gas exchange. Although not strictly synonymous, the terms "bronchioles" and "small airways" are here used interchangeably.

Bronchiolitis is nonspecific inflammation of the respiratory bronchioles and peribronchiolar alveolar sacs of variable causes, clinical manifestations and evolution. The diseases affecting bronchioles can be classified into primary bronchiolar disorders—those diseases in which the pathologic process is centered in the bronchioles—and those disorders in which the bronchioles are secondarily involved by a pathologic process that is centered in the lung parenchyma or proximal large airways[3] (Table 91.1). In this chapter, the general features and the approach to only "primary" bronchiolar disorders are discussed.

No single classification scheme for bronchiolar disorders has been widely accepted. Classification schemes have been proposed based on causes and underlying diseases, radiologic features, histopathologic findings, or some combination of these parameters. Unavoidable overlaps exist, no matter which classification scheme is chosen.

TABLE 91.1: Classification of bronchiolar disorders*

Primary bronchiolar disorders

1. Constrictive bronchiolitis (bronchiolitis obliterans)
2. Diffuse panbronchiolitis
3. Respiratory bronchiolitis
4. Acute bronchiolitis
5. Mineral dust airway disease
6. Follicular bronchiolitis
7. Others (diffuse aspiration bronchiolitis, lymphocytic bronchiolitis)

Parenchymal disorders with prominent bronchiolar involvement

1. RB-ILD and DIP
2. Hypersensitivity pneumonitis (HP)
3. Cryptogenic organising pneumonia (idiopathic BOOP)
4. Others (PLCH, sarcoidosis)

Large airway diseases with bronchiolar involvement

1. Bronchiectasis
2. Chronic bronchitis
3. Asthma

RB-ILD: Respiratory bronchiolitis–associated interstitial lung disease; DIP: desquamative interstitial pneumonia; BOOP: bronchiolitis obliterans organizing pneumonia; PLCH: Pulmonary Langerhan's cell histiocytosis

* Modified from reference 3.

TABLE 91.2: Clinical classification of bronchiolitis

1. **Infectious bronchiolitis** Respiratory syncytial virus Mycoplasma pneumoniae Parainfluenza Adenovirus Measles Rubella Rubeola	2. **Drug Induced bronchiolitis** D-penicillamine, Gold, sulfasalazine, Amiodarone, interferon, phenytoin Cocaine, minocycline, nitrofurantoin, Carmustine, bleomycin, busulfan, *Sauropus androgynus,* Paraquat
3. **Inhalational Injury** Toxic fumes and gases Mineral dusts Organic dusts Volatile flavoring agents Flock worker's lung (fine nylon fiber) Grain dusts Fire smoke (World Trade Center lung)	4. **Post-transplant** Bone marrow Heart-lung Lung
5. **Connective tissue diseases** Rheumatoid arthritis Sjögren's syndrome Systemic lupus erythematosus Polymyositis, dermatomyositis	6. **Idiopathic** Cryptogenic adult bronchiolitis Respiratory bronchiolitis Diffuse panbronchiolitis Cryptogenic organizing pneumonia Diffuse aspiration bronchiolitis
7. **Systemic diseases** Ulcerative colitis Chronic eosinophilic pneumonia Wegener's granulomatosis Chronic thyroiditis Ataxia-telangiectasia Immunoglobulin A (IgA) nephropathy	8. **Other rare** Eosinophilic bronchiolitis Lymphocytic bronchiolitis Radiation pneumonitis Primary diffuse hyperplasia of pulmonary neuroendocrine cells

The clinical classification is primarily based on the proved or presumed etiology, related systemic diseases or other associations[4] (Table 91.2). An etiologic classification is useful for reminding the physician when to suspect the presence of bronchiolitis.

General Features of Bronchiolar Disorders

Bronchiolitis, a cellular and mesenchymal inflammatory reaction that follows damage to the bronchiolar epithelium of small conducting airways, is the most common form of disease affecting small airways. This entity is relatively uncommon in adults. Neutrophils which accumulate at the site of injury causes further damage to the airway epithelium and matrix by the release of inflammatory mediators. Depending on the disease stage, the repair process may cause narrowing and distortion of small airways (constrictive bronchiolitis) or complete obliteration (bronchiolitis obliterans).

Clinical Presentations

Most commonly, the patients present with slowly progressive exertional dyspnea and dry cough. Onset of symptoms is relatively acute in bronchiolitis from infections, inhalational injury or drugs; subacute in organizing pneumonia; and indolent and chronic in patients with post-transplant bronchiolitis. Cough with copious expectoration may be seen in infectious bronchiolitis and Diffuse Panbronchiolitis (DPB). Fever and constitutional symptoms are mainly seen in infectious bronchiolitis and collagen vascular diseases. Some patients may even present with pulmonary hypertension and respiratory failure in advanced stages. Due to extensive air trapping, the physiologic dead space gradually increases to the extent insufficient to washout normal carbon dioxide from the lungs, ultimately leading to hypercapnic respiratory failure.

Chest X-ray Findings

Chest radiography in bronchiolar disorders may be normal or demonstrate nonspecific findings like hyperinflation and peripheral attenuation of vascular markings in purely obstructive bronchiolar lesions such as constrictive bronchiolitis. In other primary bronchiolar disorders, small nodules or reticulonodular infiltrates may be observed. Increased bronchial wall thickening may also be seen. In distal acinar interstitial diseases with secondary bronchiolar involvement, chest radiography usually demonstrates features of the underlying parenchymal disease process such as cryptogenic organizing pneumonia (COP) or hypersensitivity pneumonitis.

Pulmonary Function Tests (PFT)

Depending on the predominant physiology, PFTs may yield variable results. Most of the primary bronchiolar disorders and large airway diseases are associated with obstructive physiologic defects. In contrast, most of the distal acinar interstitial diseases with secondary bronchiolar involvement show restrictive or mixed pattern. Abnormal values for Forced Expiratory Flow $(FEF)_{25-75\%}$, in conjunction with normal values for Forced Vital Capacity (FVC) and Forced Expiratory Volume in One Second $(FEV_{1)}$, are often useful in identifying small airway disease. Primary bronchiolar disorders often show nonreversibility with inhaled bronchodilators. In addition, these patients also demonstrate reduced diffusion capacity. The obstruction of small airways results in abnormal distribution of ventilation to peripheral lung units. This principle forms the basis of two tests: Frequency dependence of dynamic compliance and closing volumes. The tests of small airway function (Table 91.3), however, are rarely performed in clinical practice.

High Resolution Computed Tomography (HRCT) Findings

High resolution computed tomography is perhaps the most important tool in the diagnostic evaluation of bronchiolitis.[5] Normal bronchioles cannot be seen on Computed Tomography (CT) scans, as airways less than 2 mm in diameter are not visible on CT. However, diseased bronchioles with dilated lumen (>2 mm in diameter) or thickened walls can be visualized. High resolution computed tomography scan abnormalities that reflect bronchiolar diseases can be categorized into direct and indirect signs (Table 91.4).

TABLE 91.3: Tests of small airway function

Increase in mid-expiratory flow rate
Frequency dependence of dynamic compliance
Increase in closing volume
Increased volume of isoflow

TABLE 91.4: HRCT signs of bronchiolar disorders

Direct signs	Indirect signs
• Bronchiolar wall thickening: inflammation/ fibrosis - Bronchiolectasis - Bronchiolar luminal impaction: Centrilobular nodules ± tree in bud appearance	- Mosaic attenuation - Subsegmental atelectasis

Bronchiolar wall thickening may occur due to inflammation and fibrosis, with or without dilatation (bronciolectasis). Bronchiolar luminal impaction manifests as 2 to 4 mm nodular and linear branching centrilobular opacities on CT. The "tree-in-bud" pattern represents a form of bronchiolar impaction in which branching linear structures have more than one contiguous branching site. Apart from direct signs, the most important indirect sign is the finding of mosaic attenuation, which occurs due to air trapping. However, this sign is not specific for bronchiolitis. In bronchiolar diseases, the mosaic pattern is caused by the hypoventilation of alveoli distal to bronchiolar obstruction, which leads to secondary vasoconstriction and is seen on CT scans as the areas of decreased attenuation. Paired CT scans performed in inspiration and expiration are useful for distinguishing bronchiolar disease from pulmonary vascular disease and some diffuse infiltrative diseases that may also cause a mosaic pattern.

Based on the radiologic features, bronchiolar diseases have been classified into four dominant CT patterns[2] (Table 91.5). "Centrilobular opacities with tree-in-bud" pattern is seen in infectious bronchiolitis, diffuse panbronchiolitis (Figs 91.1A and B), Diffuse Aspiration Bronchiolitis (DAB) and immunodeficiency syndromes. Centrilobular opacities appearing as ill-defined ground-glass nodules in the absence of a tree-in-bud pattern are associated with respiratory bronchiolitis, hypersensitivity pneumonitis and follicular bronchiolitis. "Ground-glass

attenuation" or consolidation is due mainly to alveolar filling that occurs in Bronchiolitis Obliterans Organizing Pneumonia (BOOP) (Fig. 91.2) or in Respiratory Bronchiolitis-Interstitial Lung Disease (RB-ILD). The prototype of the third type of CT pattern, "mosaic lung attenuation," is constrictive bronchiolitis (Figs 91.3A and B). Other conditions resulting in a pattern of mosaic attenuation include connective tissue disorders, bone marrow and lung transplantation, toxic fume inhalation and drugs. Quite often many diseases will have a "mixed pattern" on HRCT. Association of tree in bud with mosaic perfusion can be seen in different entities, such as bronchiectasis and acute bronchopulmonary infections. The combination of mosaic perfusion and ground-glass opacities in the same patient, referred to as the "headcheese sign" is very suggestive of HP.[5]

Histologic Findings

Histologically, bronchiolitis can have a wide variety of patterns (Table 91.6). However, most morphological

TABLE 91.6: Histologic patterns of bronchiolitis

- Cellular bronchiolitis
  - Follicular bronchiolitis
  - Respiratory bronchiolitis

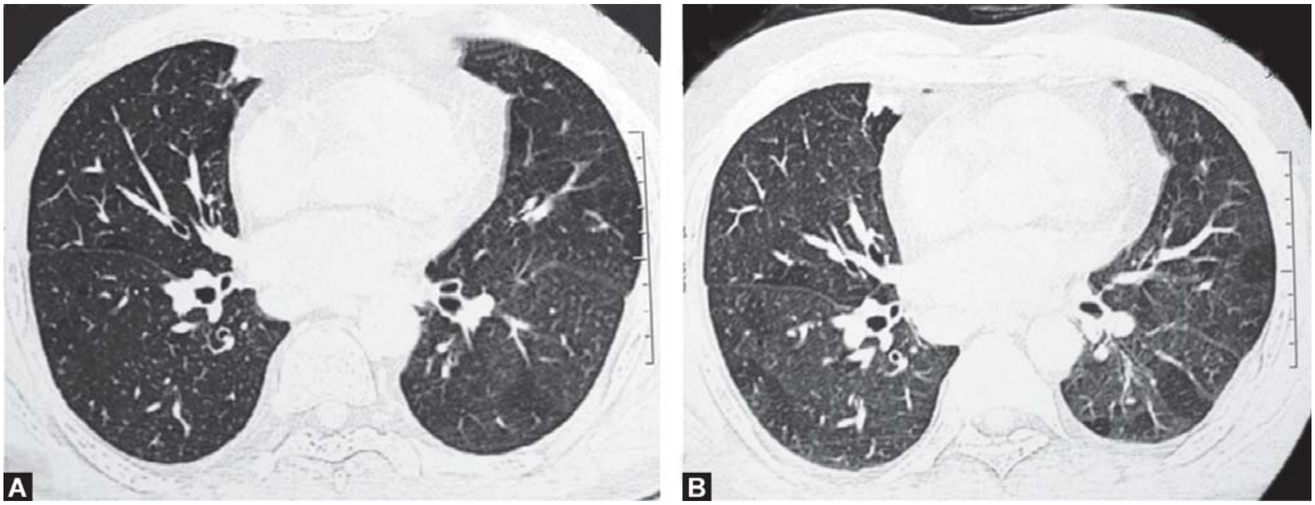

Figs 91.3A and B: Paired inspiratory (A) and expiratory (B) HRCT scans in bronchiolitis, mosaic attenuation and air trapping becomes more apparent on expiratory scans

abnormalities of the bronchioles are not specific, since bronchiolitis arises from a variety of sources of injury that result in the diversity of clinical, radiological and functional patterns. Bronchiolar changes should not be ascribed etiology or pathogenesis based solely on histologic features. Nevertheless, the histologic patterns generally show a better correlation with the radiological manifestations, the natural history of the disease, and the response to therapy.[6] In general, cellular bronchiolitis and Bronchiolitis Obliterans (BO) appear to be common "early" lesions that may resolve completely or partly, and are corticosteroid-responsive. As opposed to constrictive bronchiolitis which is relatively corticosteroid unresponsive and is usually progressive with the development of irreversible airflow obstruction and air trapping.

Since it is difficult to recognize and classify bronchiolitis in transbronchial biopsies because of the limited sampling size, the surgical biopsy is preferred. It is important to obtain wedge biopsies from multiple lobes because the bronchiolar pathology is often patchy. However, in certain clinical settings, such as those in post-transplant settings, transbronchial biopsies may be sufficient for diagnosis. It is recommended to obtain at least five pieces of well-expanded alveolar parenchyma with transbronchial biopsies.[7] The severity of clinical manifestations frequently exceeds that of histologic changes seen on lung biopsy.

In "cellular bronchiolitis," the bronchiole's structures show an increased number of inflammatory cells. It can further be characterized as acute or chronic based on the type of inflammatory cell type. It is a common pattern seen in many clinicopathologic settings like infectious bronchiolitis, inhalational injury, connective tissue diseases and aspiration. "Follicular bronchiolitis" represents hyperplasia of the Mucosa-Associated Lymphatic Tissue (MALT) and chronic peribronchiolar infiltrate along with secondary germinal centers. This pattern is associated with congenital or Acquired Immunodeficiency Syndromes (AIDS), including Human Immunodeficiency Virus (HIV) infection; collagen vascular diseases, especially rheumatoid arthritis and Sjögren's syndrome; and lymphoproliferative diseases. "Respiratory bronchiolitis" is a mild inflammatory reaction to cigarette smoke,[8] which consists of slight fibrosis, smooth muscle hypertrophy, and a characteristic presence of pigmented macrophages within the lumen of respiratory bronchioles, alveolar ducts and sacs. Respiratory bronchiolitis-associated interstitial lung disease is thought to be an exaggeration of respiratory bronchiolitis reaction sufficient to cause clinical disease. Respiratory bronchiolitis and RB-ILD often have accompanying emphysema.

"Diffuse panbronchiolitis" is a peculiar morphological form of cellular bronchiolitis largely restricted to the adult individuals of Japanese heritage. Its histologic hallmark is the presence of an interstitial inflammatory infiltrate containing foamy macrophages around respiratory bronchioles. Polyps of granulation tissue may partially occlude adjacent bronchiolar or alveolar lumina. When the histology of diffuse panbronchiolitis is encountered in an individual not of Asian descent, the possibility of inflammatory bowel disease-related bronchiolitis should be considered.

As the name suggests, "bronchiolitis obliterans" with "intraluminal polyps" is characterized, by intrabronchiolar polypoid protrusions of connective tissue that partially fill bronchiolar lumens. These polypoid proliferations usually extend distally in the alveolar ducts and alveoli, a pattern known as "organizing pneumonia." This combination of changes is referred to as BOOP pattern. The airway lumen appears to be occluded from within, as opposed to the concentric narrowing seen in constrictive bronchiolitis. Bronchiolitis obliterans organizing pneumonia is a very common tissue reaction pattern that occurs in a variety of settings. However, in many cases the cause cannot be ascertained, which is referred as cryptogenic organizing pneumonia (idiopathic BOOP). The common secondary causes of BOOP pattern are those associated with a variety of infections; connective tissue diseases and vasculitis like Systemic Lupus Erythematosus (SLE), rheumatoid arthritis, systemic sclerosis, inflammatory myopathies; post-transplant; inhalational injury like silo-filler's lung, paint aerosols, paraquat poisoning; drugs, radiation therapy and haematological malignancies.

"Constrictive bronchiolitis" refers to luminal narrowing by scarring that ranges from very subtle abnormalities to complete luminal obliteration. The hallmark of this type of bronchiolitis is mural thickening by submucosal collagenous fibrosis with progressive concentric narrowing associated with luminal distortion, mucus stasis and chronic inflammation. Bronchiolar dilatation with mucus impaction and smooth muscle hypertrophy may also be seen. There are many conditions and disorders which are associated with this type of bronchiolitis (Table 91.7); some specific ones are post-transplant bronchiolitis, bronchiolitis associated with rheumatoid arthritis and World Trade Center lung.[9]

"Peribronchiolar fibrosis" and "bronchiolar metaplasia" is a rare condition characterized by the growth of bronchiolar epithelium into the adjacent fibrotic alveolar walls (so-called lambertosis).[10] Inflammatory cells are scanty and usually present in the bronchiolar lumen. It represents a manifestation of previous

Practical Approach for Diagnosis of Bronchiolar Disorders

The broad clinical spectrum of bronchiolar inflammatory disorders in adults can be diagnosed with the help of a practical algorithmic approach (Fig. 91.4).

A detailed history of symptoms suggestive of connective tissue disease, as well as exposure to inhalational irritants and radiation, should be elicited in order to identify a possible cause. A potential relationship with drug intake should be investigated in depth and taken into account in combination with the underlying disease. On auscultation, the presence of wheezing, inspiratory squeaks, or crackles should point to the bronchioles as the likely anatomic site involved. After history and physical examination, posteroanterior and lateral chest radiographs (CXRs) and PFTs are typically obtained. These tests are of limited value in directing the diagnostic workup of primary bronchiolar disorders as they rarely establish specific diagnoses. However, they are important to exclude large airway diseases in which secondary bronchiolar changes may be seen.

As both CXR and PFT findings are frequently nonspecific, a high index of clinical suspicion should be maintained in order to diagnose and/or exclude bronchiolar disease. High resolution computed tomography scanning (inspiratory and expiratory) may play a critical role in both suggesting the specific causes of bronchiolar disease and directing optimal management. In select cases, the diagnosis may be made solely using HRCT scans in combination with the history and clinical presentation, thus obviating more invasive diagnostic testing. However, in patients where the diagnosis of bronchiolitis and its cause is not clear, the clinical relevance of a bronchiolar lesion is best determined by identifying the underlying histopathologic pattern and assessing the correlative clinico–physiologic–radiologic context. Thus, the intimate interdependence of clinical, radiological and pathologic findings in assessing the significance of bronchiolar lesions and the necessity of a multidisciplinary (clinical-radiological-pathologic)[4] approach cannot be overemphasized (Table 91.8).

Specific Forms of Bronchiolitis

Infectious Causes of Bronchiolitis

Infection is the most common cause of acute bronchiolitis, mostly seen in children of less than 1 year of age, especially during the winter season. Respiratory syncytial virus (RSV) is the etiologic agent in the majority of these patients, but other viruses (adenovirus, influenza, parainfluenza) and nonviral pathogens (mycoplasma, chlamydia) can cause a similar syndrome.[3] Symptomatic acute bronchiolitis in adults is relatively rare, but can be caused by infectious agents such as *M. Pneumonia* and RSV. No systematic study has been reported; therefore, the clinical presentation of infectious bronchiolitis in adults is ill defined.[11]

Most patients with acute viral bronchiolitis can be managed at home with supportive care since respiratory symptoms are generally mild. Although bronchodilators, epinephrine and corticosteroids have been commonly used in more severe cases of acute viral bronchiolitis, there is considerable disagreement regarding optimal treatment strategies. Beyond the use of supportive care and supplemental oxygen, there is little evidence to support a routine role for any of these drugs.[12,13]

One of the long-term complications of postinfectious constrictive bronchiolitis occurring in childhood is the development of the Swyer-James (or MacLeod's) syndrome, that is, unilateral hyperlucent lung with the evidence of air trapping and decreased vascularity especially after adenoviral infection occurring in infancy.

Inhalational Lung Injury

Several irritant gases like sulfur dioxide, chlorine gas, ammonia, nitrogen dioxide (NO_2), phosgene, photochemical air pollutants, and ozone have been occasionally associated with bronchitis or bronchiolitis. Two distinct and uncommon types of airway processes can follow exposure to noxious fumes, gases or mists: Reactive Airway Dysfunction Syndrome (RADS) and constrictive bronchiolitis. Reactive airway dysfunction syndrome is defined as the development of respiratory symptoms in the minutes or hours after a single accidental inhalation of high concentrations of irritant gas and aerosol. These symptoms are followed by asthma-like symptoms and airway hyper-responsiveness.

Mineral dust airways disease occurs because of the inhalation of a number of inorganic dusts, including asbestos, iron oxide, aluminum oxide, talc, mica, silica and coal. Inflammatory response induced by the dust likely leads to the local production of fibrogenic factors and morphogenesis of the bronchiolar lesion. Poorly defined centrilobular opacities can be seen on HRCT scans early in the course of the disease; these predominate posteriorly and at the lung bases owing to the gravitational effects of fiber deposition. Peribronchial infiltration of dust-laden macrophages is often noted on microscopy. Inhalations of "organic dusts" are associated with the development of hypersensitivity pneumonitis. Interstitial pneumonitis with granulomas are seen in most of the patients on lung biopsy.

Volatile flavoring agents used in the microwave popcorn industry can cause a respiratory illness resembling bronchiolitis obliterans, especially in workers who worked nearest the mixing tank. Lung function testing shows severe airflow obstruction, which does not recover after removal from exposure. However, there does not appear to be any risk to the general population who use microwave popcorn products.

Bronchiolitis Associated with Connective Tissue Diseases

A wide spectrum of inflammatory and fibrotic disorders involving the small airways may complicate Connective Tissue Diseases (CTDs) and include COP; constrictive (obliterative) bronchiolitis; small airways disease; cellular or follicular bronchiolitis; and bronchiectasis (most often seen in late rheumatoid arthritis). In addition, medications used to treat CTDs, penicillamine, methotrexate and gold can cause histologic abnormalities similar to those seen in the primary disease. Small airway diseases are most commonly seen in the following CTDs: Rheumatoid arthritis, Sjögren's syndrome, SLE, systemic sclerosis and polymyositis-dermatomyositis.[14] Corticosteroids are highly efficacious for COP, but therapeutic options for constrictive bronchiolitis are disappointing. Prophylactic antibiotics and good pulmonary hygiene remains the mainstay of therapy for patients with bronchiectasis.

Idiopathic

Cryptogenic adult bronchiolitis is a rare entity, the diagnosis of which is largely of exclusion. Most patients are middle-aged women with symptoms usually of 6 to 24 months' duration. Lung biopsies show cellular constrictive bronchiolitis, often quite subtle. Early treatment with corticosteroids might be of benefit in some patients.[15-18]

Respiratory bronchiolitis is a specific form of smoking-related small airway disease. Respiratory bronchiolitis usually occurs without symptoms or physiologic evidence of lung disease.[8] In some patients, however, respiratory bronchiolitis can cause symptomatic diffuse parenchymal lung infiltrates, a syndrome referred to as RB-ILD. Respiratory bronchiolitis per say does not require any treatment other than smoking cessation. Most studies suggest a favorable response to steroids in RB-ILD.

Diffuse aspiration bronchiolitis is a term used to define a clinical entity characterized by the chronic inflammation of bronchioles caused by recurrent aspiration of foreign particles.[19] Most previously described patients with this disorder have been elderly and bedridden.[19] However, this disorder can be seen in the adults of varying ages with gastroesophageal reflux disease that may be clinically occult.[20]

Drug-Induced Bronchiolitis

Several drugs have been reported to have an association with the development of bronchiolitis, usually with organizing pneumonia. However, a definite "cause and effect" relationship between these drugs and the development of BO is uncertain, because most reports are of single cases or small case series. Pure bronchiolitis obliterans, with airflow obstruction, has been associated with gold therapy.[21] However, it is difficult to state that these cases resulted from gold-induced airway injury, because patients with rheumatoid arthritis also are prone to develop pure bronchiolitis obliterans. Pulmonary complications of penicillamine therapy are uncommon, but may include BO and diffuse interstitial infiltrates.[22,23] This form of BO may be characterized by a rapidly deteriorating course and pulmonary insufficiency. Up to 25% cases of amiodarone lung disease may develop organizing pneumonia (BOOP pattern), which mimic an infectious pneumonitis. Treatment primarily consists of stopping the offending drug, and corticosteroid therapy (prednisone 40 to 60 mg a day, tapering over 2 to 6 months) can be life saving in severe cases.

In Taiwan, an outbreak of rapidly progressive respiratory distress associated with consumption of uncooked *Sauropus androgynus,* a vegetable, claimed to be effective in weight control, has been reported. No effective treatment has been reported and the clinical response to prednisolone was limited.[24]

Bronchiolitis Associated with Organ Transplantation

Patients with bone marrow transplantation, heart-lung transplantation, or lung transplantation may develop BO as a chronic rejection phenomenon. This type of bronchiolitis remains the most common form of chronic rejection in patients with lung transplants, occurring in up to 50% of patients.[25] Constrictive bronchiolitis is also seen as a manifestation of graft versus host disease in 10% of people who have received allogeneic bone marrow transplants.[26] This problem is a major threat to long-term survival in these transplant recipients and is the leading cause of late death after lung transplantation.[27]

Three major kinds of airway injury may be seen in allograft recipients: Acute (cellular) rejection, bronchiolitis obliterans, and lymphocytic bronchitis. The lesions of BO are characterized by the features of constrictive bronchiolitis. Ultimately, smooth muscle cells, myofibroblasts, and mature collagen obliterate the airways ("vanishing airways disease").[28,29] Occasionally, classic BOOP, with patchy organizing pneumonia and granulation tissue plugs extending into the alveolar ducts, is observed as the predominant lesion.

The pathogenesis of post-transplant bronchiolitis is a finely orchestrated process involving multiple events. Alloreactive injury to the bronchial epithelium is considered as the key pathogenetic mechanism. Other possible mechanisms like recurrent, persistent bacterial or viral infections; graft-versus-host disease or transplant rejection; impaired repair of injured airways due to bronchial artery ligation; altered mucociliary clearance; and recurrent aspiration also contribute to the development of BO.

Because of the patchy distribution of lesions and difficulties in obtaining adequate samples of bronchioles, confirming the diagnosis of constrictive bronchiolitis in transplant recipients by transbronchial lung biopsies is problematic. Thus, the phenomenon of progressive airway obstruction in lung transplant recipients is termed "Bronchiolitis Obliterans Syndrome (BOS)," a clinical diagnosis, and is defined physiologically by a decrement in FEV_1 of 20% or more below a stable baseline.[27,30]

Most patients with BO progress to respiratory failure, and some patients develop bronchiectasis with frequent bacterial exacerbations. Aggressive therapy results in improvement of lung function in only 8% to 20% of patients.[31] Intensification of immunosuppressive therapy is the mainstay of therapy. The maintenance therapy with macrolides have demonstrated significant functional improvement in BOS,[32] and is used as an adjunct to immunosuppressive regimen.

Diffuse Panbronchiolitis

Diffuse panbronchiolitis (DPB) is a progressive inflammatory disease characterized by chronic sinusitis, bronchiolitis and progressive obstructive airway disease that rapidly progresses to bronchiectasis, respiratory failure and death. While DPB is prevalent in Asian countries especially Japan, it has been rarely described among non-Asian patients.[33,34] It has a strong genetic predisposition with HLA-B54 common among the Japanese.[33] However, the precise etiology is unknown. It usually affects people in the second to fifth decade. If DPB is left untreated, only 12% to 25% of patients survive for up to 10 years.

The plain CXR film reveals bilateral, diffuse, small nodular shadows predominantly in the lower field of the lung with hyperinflation. In advanced cases, ring shaped or tram-line shadows indicating bronchiectasis appear. High resolution computed tomography is extremely useful for the detection of characteristic pulmonary lesions of DPB (Fig. 91.1). In fact a system for grading these HRCT scan changes has been described.[35] Stage I is characterized by multiple centrilobular nodules usually less than 5 mm in diameter, which are present at the end of bronchovascular branching structures. In stage II, these centrilobular nodules are seen connected to distal branching bronchovascular structures in a Y-shaped configuration, which provides the tree-in-bud appearance. Early-stage bronchiectasis is seen in stage III, while the presence of large cysts makes it stage IV. The diagnosis of DPB is often made on clinicoradiologic grounds by demonstrating its distinctive features and excluding other sinobronchial disorders. Lung biopsy shows transmural and peribronchiolar infiltration with lymphocytes and plasma cells. However, it is usually not necessary in countries where the disease is of high prevalence. (Table 91.9)

Erythromycin therapy has been shown to improve symptoms, lung functions, CT scan changes and survival rates in the patients of DPB. Most patients are treated for more than 2 years and until the resolution of symptoms and the disappearance of centrilobular nodules. Treatment should be resumed if symptoms reappear after the cessation. Other members of the macrolide family are also efficacious in treating patients with DPB. An immune system modulating effect is more

TABLE 91.9: Diagnostic criteria for diffuse panbronchiolitis*

Major
1. Persistent cough, sputum and exertional dyspnea
2. History suggestive of chronic paranasal sinusitis
3. Bilateral small nodular shadows on plain chest radiograph or centrilobular nodules on HRCT

Minor
1. Coarse crackles
2. $FEV_1/FVC < 70\%$ and $PaO_2 < 80$ mm Hg
3. Cold hemagglutinin titre ≥ 64

FEV_1: forced expiratory volume in one second; FVC: forced vital capacity; PaO_2: arterial oxygen tension

Definite diagnosis made if all three major and two out of three minor criteria present.

*Modified from reference 34.

likely than antibacterial activity, as the mechanism of erythromycin therapy. It has been demonstrated by the ability of erythromycin to reduce neutrophil influx by decreasing levels of interleukins that are chemoattractants.[36]

Other Rare Forms of Primary Bronchiolar Disorders

A relatively new entity termed "eosinophilic bronchiolitis" have been described wherein the lung biopsy specimen demonstrated peri- and transmural bronchiolar infiltration by massive numbers of eosinophils along with plasma cells and degenerating eosinophils with Charcot-Leyden crystals within bronchiolar lumina, with minimal alveolar involvement.[37] This disease responds fairly well to steroid therapy.

BULLOUS DISEASE OF THE LUNG

A "bulla" is an air-containing emphysematous space within the lungs that has a diameter of more than 1 cm in the distended state and that causes a local protrusion from the surface of the removed lung. The terminology "bullous lung disease" is reserved for an entity characterized by the presence of bullae in one or both the lung fields, with normal intervening lung.[38] This entity is different in etiology and pathogenesis from "bullous emphysema," a condition in which bullae occur in conjunction with the emphysematous changes in the nonbullous lung.[39-41] "Giant bullous lung disease" is said to be present if the bullae occupy at least one-third of the hemithorax and compress the surrounding lung parenchyma.[39]

It is important to differentiate between the terms bulla, bleb and cyst. "Bleb" is an accumulation of air between the two layers of visceral pleura and lined by the elastic lamina. Whereas, "bulla" is present deep to the internal elastic layer of the visceral pleura and is confined by connective tissue septa of the lung. In contrast, "cyst" is lined by epithelium and can be present in the lung parenchyma or mediastinum. Three types of bullae are recognized pathologically, which differ in location, size of neck, and amount of contained residual lung tissue; the clinical significance of which is unclear.

Pathogenesis

The pathogenesis of bullae formation is complex and poorly understood. Bulla arises from destruction, dilatation and confluence of airspaces distal to terminal bronchioles, the walls of which are composed of attenuated and compressed parenchyma. Of all the hypotheses, that of an underlying paraseptal emphysema is the most popular. The structural weakness of the interalveolar septa caused by elastolysis, which itself may be secondary either to a constitutional disorder or to enhanced proteolysis is the predominant mechanism for the development of paraseptal emphysema. Airspaces in paraseptal emphysema may become confluent and develop into bullae, which may be large. Airway obstruction caused either by the loss of airway support or by inflammatory changes in the walls of small airways, also, contribute to progressive enlargement of these airspaces; ultimately resulting in the formation of bullous emphysema.

However, in the patients of "bullous lung disease" with normal intervening lung, a mechanism different from that of bullae occurring in conjunction with emphysema is more likely. Several hypotheses have been proposed over the years, but none has been proved. Two hypotheses which have attracted most of the attention are "paper bag hypothesis" and a "ball valve mechanism" for bulla formation. Chronic inflammation of the airways especially terminal bronchioles causes airway obstruction, which acts as ball valve allowing air to enter during inspiration, leading to progressive air trapping and tension airspaces. However, this theory of bulla formation by positive pressure within the airspace has been refuted by the studies of dynamic computerized tomography and intrabulla pressure measurements. Moreover, in studies performed in subjects with bullae who are taken to altitudes of 18,500 feet (at an ascent rate of 1000 feet per minute), little increase in bulla volume is noted, probably reflecting good communication between bullae and airways and adequate pressure equalization.

The pressure in bullae is normally negative and same as that of pleural pressure.[42] The lung surrounding the bulla is less compliant than the bulla itself. Therefore, the pressure required to inflate the surrounding lung is greater than that necessary to inflate the bulla. During inspiration, when bullae and the adjacent lung parenchyma are subjected to same negative pleural pressure, bulla fills preferentially than the surrounding lung like a "paper bag." However, this "paper bag compliance" is seen up to a critical lung volume, after which they become stiff and much less compliant than lung.[43]

Bullae communicate with the rest of the bronchial tree, but air enters or leaves the bullae quite slowly. So bullae generally do not act as clinically important dead space. During tidal breathing PO_2 in bullae is higher than arterial PO_2.

Etiology

Bulla may originate in a variety of clinical and pathogenetic settings. Smoking and alpha 1-antitrypsin deficiency are the two most important risk factors for bullous emphysema. A hereditary predisposition to bullous emphysema is also suggested by its association with a variety of rare familial disorders, including Fabry's disease, cutis laxa, Ehlers-Danlos syndrome and Marfan's syndrome. Marijuana smoking has been implicated as the cause of large upper zone bullae in some individuals.[44] Upper zone "fibrobullous disease" is also reported in ankylosing spondylitis, usually seen in patients of long-standing disease of 15–20 years duration with marked spinal involvement. It is possible that some patients labeled as having giant bullous disease harbor an unusual condition like pulmonary sarcoidosis, Langerhans cell histiocytosis, idiopathic pulmonary fibrosis or progressive massive fibrosis. Post-tubercular fibrosis may sometimes present as bullous disease. The cause cannot be ascertained in a subset of patients with bullous disease, they are labeled as idiopathic bullous disease.

Clinical Presentation

As a rule, small bullae usually produce no symptoms, signs or discernible alterations in pulmonary function; and are detected during routine chest radiography. However, rupture of one or more bullae may lead to spontaneous pneumothorax.

The most common presenting symptom in bullous lung disease is of gradually progressive exertional dyspnea. Occasionally they may develop sudden severe increase in breathlessness either due to pneumothorax or overdistension due to air-trapping. Chest pain may occur in a patient with bullous lung disease. This is also due to overdistension of the large bullae or development of pneumothorax. Overdistension causes a diffuse dull aching type of chest pain, usually located retrosternally. Hemoptysis is an uncommon presentation, and usually indicates hemorrhage inside the bullae. Increase in cough and sputum production, in patients with known bullous disease, usually heralds the presence of infection in a bulla.

The findings on physical examination are usually dominated by the presence of associated disease. Occasionally, giant bullae may cause localized hyperresonant note and decreased breath sounds.

Radiologic Features

Small bullae rarely become visible on the chest radiograph, but they are usually easily visible by computed tomography. Apical bullae may sometimes be misinterpreted as cavitation on plain radiographs. They can be differentiated if it is remembered that cavities are centered within areas of consolidation and they do not merely overlap them.

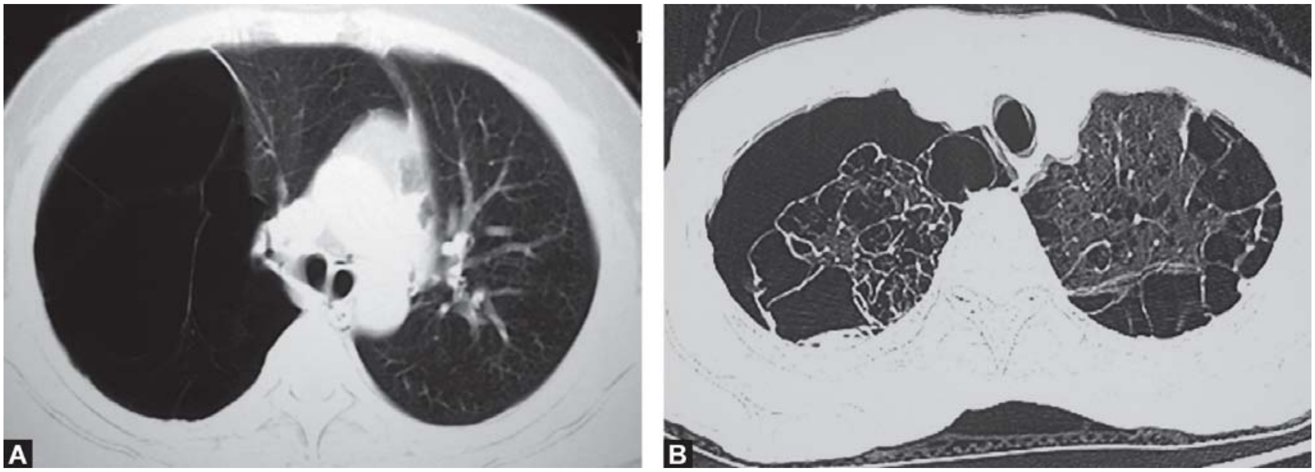
High resolution computed tomography is an important tool as it can locate the bullae with considerable accuracy, even when their presence is not suspected on the basis of clinical and radiographic data. It also helps in assessing the extent and localization of bullae and associated diffuse nonbullous emphysema. It also allows assessment of associated diseases such as bronchiectasis, infected cysts, pleural disease and pulmonary hypertension.[38] Computed tomography scans can help in differentiating bullous lung disease from bullous emphysema. The intervening lung parenchyma is normal in bullous lung disease as opposed to changes of emphysema seem in emphysematous bullae (Figs 91.5A and B).

The bulla is seen as an avascular transradiant area separated from the rest of the lung parenchyma by a thin curvilinear wall. The wall is usually of hairline thickness. They are of variable size ranging from 1 cm to almost half of the hemithorax. Bullae are much more common in the upper zones, especially those associated with paraseptal emphysema. The difficult distinction between bullous disease and pneumothorax can be made with CT through the "double-wall sign" (i.e. air visible on either side of the wall of bulla). CT has also been used to create 3-D reconstructions of bullae, which can then be used to calculate bullae volumes.

Pulmonary Function Tests

Detailed PFTs have an important place in the assessment of these conditions and to differentiate bullous disease from bullous emphysema. This distinction is important since the patients with bullous emphysema are in general poor surgical candidates as compared to patients with bullous lung disease. Pulmonary function tests can also help to make an objective assessment of the severity of the underlying disease, quantifying the size of bulla and monitor the response to treatment.

Spirometry done in patients with bullous lung disease usually shows restrictive defect, presumably as a result of the bulla compressing intervening normal lung; whereas a predominant obstructive defect is seen in patients having bullous emphysema. The diffusing capacity is reduced to a greater extent in bullous emphysema as compared to bullous lung disease, and this test correlates better with morphologic estimates of emphysema than do most other tests. The diffusing capacity fails to increase normally during exercise. With



Figs 91.5A and B: HRCT scan in bullous lung disease (A) and bulllous emphysema (B)

exercise, the arterial oxygenation, ratio of dead space to tidal volume and the alveolar-arterial difference in PaO_2 tend to remain normal or near normal in patients with a few circumscribed bullae and otherwise normal lungs, as compared to patients with bullous emphysema where they uniformly decrease, indicating progressive alveolar hypoventilation.

In patients with bullous lung disease, the lung volumes should be assessed by both the helium dilution technique and via body plethysmography. A known volume of gas and a trace amount of helium (an inert gas, very little of which absorbs into the pulmonary circulation) is breathed in and out of a reservoir in the helium dilution technique. The helium is diluted by the gas that was previously present in the lung. With the knowledge of the gas in the reservoir and the initial and final helium concentrations, the functional residual capacity and the Total Lung Capacity (TLC) can be calculated. However, because of inadequate time to equilibrate with slowly communicating and noncommunicating air spaces such as bullae, this technique may underestimate the TLC. So, lung volumes should also be measured with body plethysmography, which measures the total volume of the thorax. The difference in TLC measured by body plethysmography and that by the helium dilution technique approximates the volume of the bullae.[38]

Bullae volume = TLC by body plethysmography – TLC by helium dilution

In some patients with bullous emphysema respiratory muscle strength improves after bullectomy, as assessed by the measurements of maximal inspiratory and transdiaphragmatic pressures.[45] In patients with bullous emphysema, due to reduction in the pulmonary vascular bed, the resting pulmonary artery pressures are increased which further exaggerate during exercise. However, isolated bullae act like amputated segments of the lung and resting pulmonary arterial pressure and blood flow are within normal limits.

Natural History

Systematic long-term studies on the natural history of bullous lung disease are lacking. Patients with bullous disease should be monitored by chest radiography at regular intervals to ensure that the disease is stable. Bullae usually enlarge over months and years with a variable rate. And the period of stability may be followed by a sudden expansion. In some patients, often young men, there may be the inexorable progression of idiopathic giant bullous disease. The alternative name given for the devastating nature of this condition is "vanishing lung syndrome." In some patients bulla may disappear either spontaneously[46,47] or following infection and hemorrhage,[47] or with medical therapy alone.[48]

Complications

The main complications of bullae are pneumothorax, infection or hemorrhage. When infected, bullae usually contain fluid and develop an air-fluid level. Fluid may be frequently resorbed, and cause complete resolution of the bulla.[47] The hair-line wall often becomes thickened, and indeed this may be the only sign of infection. An infected bulla differs from an abscess in that the patient is less ill, the wall of the ring shadow is thinner and has a sharp margin, and there is less adjacent pneumonitis. Sometimes, a fungus colonizes a bulla and may form a mycetoma or fungal ball. Hemorrhage inside the bulla is a less common complication and it manifests as hemoptysis or decrease in hemoglobin level.[49] As with infection, bulla may disappear after bleeding occurs. Pneumothorax may occur due to the rupture of the bulla in pleural cavity or as a complication of paraseptal emphysema. Patients tend to have a prolonged air-leak in such cases.[50]

Isolated cases of carcinomas arising in bullous lung diseases have been reported during the past 40 years. The majority of lung cancers associated with bullous disease are non-small-cell tumors. The frequency of lung cancer in subjects with bullous disease is approximately 32 times higher than in those without these abnormalities.[51] High resolution computed tomography signs which could suggest the presence of carcinoma include mural nodule, mural thickening, fluid within bulla and change in bulla diameter.[52,53] The possible carcinogenic mechanism of bullous disease remains uncertain. The proposed mechanisms are: (1) carcinogens may inhibit antielastase enzymes, resulting in interalveolar-septal destruction with subsequent bulla formation; (2) constitutional or congenital factors may cause bullous disease and simultaneously may also predispose to lung cancer; and (3) impaired ventilation of bullae may facilitate the deposition of carcinogens.

Treatment

An asymptomatic patient diagnosed to have bullous lung disease should be reassured and educated about the disease. All attempts should be made to quit smoking. The patients should be asked to avoid the activities that promote rupture of bulla like “scuba-diving.” Appropriate treatment for the associated disease like asthma or COPD should be given. There are case reports of the spontaneous resolution of progressively enlarging giant bullous emphysema after medical therapy for COPD was instituted.[48] Appropriate antibiotics and chest physiotherapy should be started as soon as the diagnosis of infected bullae is established.

Because of the impairment of respiratory function, and the higher incidence of coexisting infection and cancer, the giant bulla should be resected in all patients, even if they are asymptomatic. Enlarging bullae causing incapacitating dyspnea or chest pain or impending respiratory insufficiency also need to be resected. Any lung mass associated with bullae should be considered an indication for surgery. Other indications of bullectomy include infected bullae and that causing recurrent pneumothorax (Table 91.10).

TABLE 91.10: Indications of bullectomy

- Giant bullae
- Symptomatic bullous lung disease
    - Incapacitating dyspnea
    - Chest pain
- Complications
    - Infection
    - Recurrent pneumothorax
    - Cancer

Even in bullectomy cases without the evidence of parenchymal lesions, the surgical resection should be as complete as possible and accurate pathological examination of the resected specimen should be performed because of the suspected existing occult or small sized lung cancer. Bullectomy can be done either via video-thoracoscopy (using a stapling device) or conventional thoracotomy. Mortality and complication rates are usually lower with thoracoscopy than with other surgical approaches.

Bullectomy is different from Lung Volume Reduction Surgery (LVRS), which is the surgical removal of 20% to 30% of nonbullous emphysematous lung from each side. The greatest benefit from surgery is seen in patients with a large bulla (occupying 50% or more of hemithorax), a moderate reduction in FEV_1, a rapid onset of dyspnea and no evidence of generalized emphysema.[54] The physiologic basis of functional improvement after bullectomy is similar to that following LVRS.[55]

Other treatment approaches for giant bullae include reduction pneumoplasty and Brompton’s procedure (endocavitary aspiration with sclerosis and pleurodesis); the latter is preferred in patients with poor pulmonary function.[56]

Distinction between widespread obstructive airways disease with concomitant bullae and bullous lung disease has practical significance, since surgical lung resection in generalized emphysema offers a less certain therapeutic response than does resection of giant bullae in the absence of widespread obstructive lung disease. As a rule, surgical intervention is avoided in bullae associated with either obstructive or fibrotic lung disease, unless life-threatening complication arises.

Immunomodulators in Respiratory Diseases

Agam Vora

INTRODUCTION

Immunomodulation is a process that can alter immune system by interfering with its function, which results in the suppression or augmentation of immunological reactivity.[1-3] Apart from specific suppressive or stimulative activity, certain agents can normalize or modulate the pathophysiological process. It involves homeostasis between Th1 (cell mediated) and Th2 (humoral) immunity. Also, it leads to the fine tuning of inhibitors, activators and regulatory signals ensuring immunostasis (Tables 92.1 and 92.2). Agents which restore this balance are classified as Immunomodulators.

Immunomodulator is a broad term, it practically involves all environmental insults that can alter body's internal milieu and hence from cigarettes to antibiotics, to simple pain killer or may be a multivitamin could be an Immunomodulator. In practice it may be more appropriate to restrict the use of the term, to molecules or interventions altering host immune reactions to boost immunity. There are several pharmacological agents and approaches used to enhance/modulate immunity (Table 92.3).

TABLE 92.1: The major goals of immunomodulator and immune-based therapies

- Potentiating the host's immune system to better control of insult/infection.
- Strengthening the patient's native immunity against a variety of opportunistic infections.
- Oppose the biological effects of the bacilli on the host by:
  - Inducing the production of beneficial cytokines and amplifying their biological effects.
  - Inhibiting the production and biological effects of harmful proinflammatory cytokines.
  - Stimulating the overall generation and activity of immune cells by stimulating the bone marrow thymus axis.

TABLE 92.2: Uses of immunomodulators

- Preventing infections proceeding to disease state
- Preventing the occurrence of secondary infections
- Achieving early control of infection/disease in conjunction with specific chemotherapy.
- Achieve early clinical response in terms of weight gain and reduction in toxemia

TABLE 92.3: Immunomodulators agents[4]

- Levamisole
- Immunoglobulins–IgG
  - Polyclonal
  - Monoclonal
- Herbomineral drugs
- *Mycobacterium welchii* vaccine
- Vaccine approach (Bacterial lysates)
- Cytokines (Interferons and Interleukins 2)/Leukotriene
- Donor lymphocyte infusion
- Synergic bone marrow transplant
- Granulocyte macrophage colony stimulating factors and granulocyte colony stimulating factors

Of these various immunomodulators which are currently available, cytokines, bone marrow transplantation (allogeneic or syngeneic) or donor lymphocyte infusions are generally beyond the reach of most of our patients. The herbomineral drugs, bacterial lysates or polyclonal immunoglobulins may prove to be cheaper options.

Levamisole

Levamisole is primarily an antiparasitic drug, which possesses immunomodulatory property. It is known to restore depressed immune function as an immunoadjuvant. Its effect on the immune system depends in part on the presence of antigenic stimulation. Levamisole can stimulate antibody formation to various antigens, enhance T-cell responses by stimulating T-cell activation and proliferation, potentiate monocyte and macrophage functions, including phagocytosis, chemotaxis and increase motility, adherence and chemotaxis. Levamisole can stimulate a normal and a depressed immune system, often classified as both an immunoregulator and immunostimulant. Levamisole affects T-cells to a greater degree than the B-cells, leading to cutaneous reactivity to delayed-type hypersensitivity antigens and improvement in helper, suppressor and cytotoxic T-cell functions.

Immunoglobulins

Immunoglobulins are proteins produced by cells of the B-lymphocyte lineage that are the major effector molecules of the humoral immune system. Immunoglobulin molecules are antibodies that react with specific antigens. Immunoglobulin preparations from human blood were first used in clinical medicine in 1952 to treat immune deficiency conditions. At that time, the available preparations required Intramuscular Immunoglobulin (IMIG) administration. In the past two decades, several immunoglobulin preparations for intravenous administration have become available. Although initially used for immune deficiency states, Intravenous Immunoglobulin (IVIG) has also been utilized as a prophylactic and therapeutic reagent in a variety of other conditions. The use of IVIG has undergone tremendous growth in the past several years. This rapid growth in use is the result of improvements in the preparations of IVIG, which have led to reduced morbidity and reports of its benefits in a number of unexpected circumstances. IVIG has been used in such diverse diseases as primary immunodeficiency, pediatric AIDS, infections in low birth weight infants, bone marrow transplantation, chronic lymphocytic leukemia, idiopathic thrombocytopenic purpura, Kawasaki syndrome and demyelinating polyneuropathies.

There are various mechanisms of importance in the different therapeutic uses of IVIG: (1) replacement therapy for primary and secondary immunodeficiencies, (2) specific passive immunotherapy, and (3) management of specific inflammatory and/or immunologic disorders. In our own experience, patients of Multidrug-Resistant Tuberculosis (MDR-TB) as well as those with HIV infection, who had received immunoglobulins along with antituberculosis therapy had sputum conversion along with quicker clinical improvements. Also, they had significantly lower opportunistic infections. We have used this treatment for a variety of disorders like chronic persistent asthma, burnt out Interstitial Lung Disease (ILD), MDR-TB, bronchiectasis and Chronic Obstructive Pulmonary Disease (COPD) requiring frequent hospitalizations for repeated infective exacerbations.[4]

Mycobacterium welchii (MW)

Mycobacterium Welchii is a nonpathogenic, rapidly growing organism. It was identified as an unique organism as an immunomodulator for leprosy. Multibacillary leprosy is associated with anergy to *Mycobacterium leprae* antigen. The anergy is very specific to *M. leprae* antigen. Even when patients are cured for leprosy using Multidrug Therapy (MDT), anergy to *M. leprae* antigen persists, to poor Th1 type response.

In search of a potent immunomodulator to enhance Th1 response, different mycobacteria were evaluated. All were evaluated for their ability to enhance Th1 response (human) as determined by blast cell transformation as well as for lymphoproliferative response. *Mycobacterium welchii,* was found to be the most potent, so it was selected for further evaluation and clinical application. *Mycobacterium welchii* also shares antigens (particularly 13 KDa protein), which are specific for immunity with *Mycobacterium tuberculosis.* This antigen sharing may result to provide protection against tuberculosis and drug-resistant tuberculosis.

Herbo Mineral Preparations

From the time immemorial, we have been using herbomineral preparations as immunomodulators in ayurvedic medicine. These herbs have been shown to differentially modulate the cytokine profile, inducing and amplifying the effects of certain cytokines while at the same time inhibiting others. With the advent of Human Immunodeficiency Virus (HIV) and with increased prevalence of MDR-TB, there is resurgence of interest in the traditional medicine of Chinese and Indian origin, to use these drugs as adjuvants to potentiate the immunity of host.

Bacterial Lysates

Bacterial lysates are constituted by a mixture of bacterial antigens derived from different bacterial species, according to the considered extract. The more often included species are: *Staphylococcus aureus*, *Streptococcus viridans*, *Streptococcus pneumoniae* (6 strains), *Streptococcus pyogenes, Klebsiella pneumoniae, Klebsiella ozenae, Moraxella catarrhalis* and *Hemophilus influenzae.*

Bacterial lysate is both a specific and nonspecific immunostimulating agent, indicated for both the prevention and treatment of respiratory infections, including sequelae to common cold and influenza. In particular, it is useful for the treatment of acute and chronic bronchitis, tonsillitis, pharyngitis, laryngitis, rhinitis, sinusitis and otitis. It can also be used for infections resistant to common antibiotics and for the sequelae of bacterial and viral infections.

The rationale for oral immunization strategies is solely based upon the communication between different mucosal tissues. Dissemination of lymphoid cells from the gut-associated lymphoid tissue to distant mucosa-associated effector sites, such as the respiratory tract, the genitourinary tract and various excretory glands, where these cells proliferate and differentiate into effector cells, is observed on the application of oral antigens.

Local immune protection due to oral vaccination is a result of increased production of antigen-specific secretory Immunoglobulin A (IgA). Oral application of bacterial antigens enhanced peripheral polymorphonuclear leukocyte functions, as reflected by a significantly increased oxidative burst activity. Significant reduction of intrapulmonary inflammatory reactions to infection with *S. pneumoniae* and an enhancement of pulmonary defense mechanisms mediated by increased gamma interferon production have been reported.[5]

Bacterial lysates are powerful inducers of a specific locoregional immune response that significantly enhance the concentration of antibodies directed to antigenic structures of bacteria, most commonly observed during infections of the upper respiratory tract. Those antibodies have the capability of opsonizing living bacteria, thus allowing the engulfment and killing mediated by human phagocytes, such as the granulocytes. This activity is linked to the capacity of inducing a significant reduction (or a complete disappearance) of signs and symptoms related to respiratory infections.

Interferons

Interferons (IFNs) are small proteins that inhibit viral replication and promote the cellular (T-cell) immune response. Interferon use for cancer treatment was limited until the late 1970s, when technological advances enabled mass production of IFN. There are three major types of IFNs: alpha, beta and gamma. Each type has similar but distinctive capabilities for altering biological responses.

Interleukin-2

Interleukin-2 (IL-2) is a substance produced by lymphocytes. In addition to being an essential factor for the growth of T cells, IL-2 augments various T-cell functions and enhances NK cell function. IL-2 also activates Lymphokine-Activated Killer (LAK) cells, which are a type of killer T cell produced when lymphocytes are incubated with IL-2. Lymphokine-activated killer cells destroy tumor cells and improve the recovery of immune function in certain immunodeficiency states. Patients with renal cell cancer, melanoma and non-Hodgkin's lymphoma have demonstrated responses to IL-2 therapy.

Colony-Stimulating Factors

Colony Stimulating Factors (CSFs) are growth factors which mediate the proliferation, maturation, regulation, and activation of granulocytes, macrophages, lymphocytes, monocytes, erythrocytes and platelets. Many types of CSFs have been produced synthetically. Some have been approved for use and some are in various stages of clinical trials. Generally, CSFs have been named for the major cell lineage they affect: Granulocyte-Macrophage CSF (GM-CSF) affects both granulocyte and macrophage lineage; Granulocyte CSF (G-CSF) targets only granulocytes. These hemopoietic factors have mainly been used to improve immune response to variety of adverse reactions seen with immunosuppressive therapy.

Tumor Necrosis Factor

Tumor Necrosis Factor (TNF) is a substance naturally secreted by macrophages. When activated by endotoxins, the macrophages release TNF, which then binds to receptors on cell membranes. Once bound to the cell membrane, TNF initiates cellular activity and is possibly cytotoxic to that cell.

The experience with these TNF, CSF, interleukin and interferon is mainly limited to oncology practice.

Biological Response Modifiers (BRM)

These are the substances of biological origin, which can modify immune function. Therapeutic enzymes work together with body enzymes as immune stimulants and are considered important BRMs. Enzymes have a central importance in ensuring the equilibrium between activation and inhibition of reactions of the immune system, which leads to tissue damage in almost every disease. Mechanism of action in these conditions is by enzymatic interruption of the complement cascade, breakdown of pathogenic immune complexes and activation of macrophages.

Lysozyme: Lysozyme is an enzyme found in egg white, tears and other secretions. It is responsible for breaking down the polysaccharide walls of many kinds of bacteria and thus it provides protection against infection. Lysozyme is an antimicrobial, innate immune molecule, which hydrolyzes the 1,4-beta-links between N-acetylmuramic acid and N-acetylglucosamine, thus cleaving an important polymer of the cell walls of many bacteria (degrading peptidoglycan of the bacterial cell wall).

Synergism of the antimicrobial effect in the presence of lysozyme is variable for the drugs differing in the mechanism of their action and depends on the pathogen species. The most pronounced synergistic effect is observed with respect to gram-positive bacteria with the use of many drugs. Combination of lysozyme with aminoglycosides results in increasing antimicrobial effect with respect to practically all the microbial cultures tested. The clinical trials of the efficient combinations of the antibiotics and lysozyme studies experimentally prove their high efficacy in combined therapy of patients with pneumonia and pyelonephritis of bacterial genesis.

Lysozyme protects from the ever-present danger of bacterial infection. It is a small enzyme that attacks the protective cell walls of bacteria. Bacteria build a tough skin of carbohydrate chains, interlocked by short peptide strands, that braces their delicate membrane against the cell's high osmotic pressure. Lysozyme breaks these carbohydrate chains destroying the structural integrity of the cell wall. The bacteria burst under their own internal pressure.

Lactoferrin: Lactoferrin is a globular multifunctional protein with antimicrobial activity (bactericidal, fungicidal), is part of the innate defense, mainly at mucosa. Lactoferrin is found in milk and many mucosal secretions such as the tears and the saliva. Lactoferrin is also present in secondary granules of Polymorphonuclear Leukocytes (PMN) and also secreted by some canard cells. Lactoferrin can be purified from milk or produced recombinantly. Human colostrum has the highest concentration, followed by human then cow milk.

Over the past three decades, various laboratories have identified lactoferrin as an antimicrobial agent. The occurrence of lactoferrin in saliva has initiated many studies on antimicrobial activity against oral streptococci and control of caries.

Bioenhancers

Bioenhancers increase the bioavailability of an orally administered pharmaceutical compound through the inhibition of P-glycoprotein transport activity in the gut, like piperine. They enhance the effect of other molecules taken together, but have no effect on their own.

Place in Therapy

Immunomodulators may be considered for patients with advanced immunocompromised disease state; patients with multiple comorbidities; patients on immunosuppressant and for patient not showing satisfactory clinical response in spite of being on adequate therapy. Large scale studies or randomized controlled trials of their use in various respiratory diseases are not yet available.

Immunomodulators are likely to form the central part of the treatment modality of this decade. Helping the host to modulate the immune system for a favorable outcome in an otherwise high-risk situation holds the key to a successful management plan.

Foreword

In reading through the *Textbook of Pulmonary and Critical Care Medicine* edited by Professor SK Jindal of the Postgraduate Institute of Medical Education and Research, Chandigarh, my thoughts drifted to a recent best-selling book authored by Thomas Friedman, titled, *The World is Flat: A Brief History of the Twenty-first Century*. The author argues that the world is shrinking from a size small to a size tiny and this has been accompanied by a flattening of the playing field. The dynamic forces of recent globalization give a unique quality to our flat world today—the power of individuals to collaborate and compete globally. Using this 21st century power and the tools of the flat world, namely the personal computer, the fiberoptic cable, and modern publishing house software, Professor Jindal has fostered an outstanding collaboration among experts spanning several continents. He has also produced a practical, authoritative and comprehensive resource for students, physicians in training and seasoned clinicians alike, that rivals any standard textbook on this subject and can compete on equal footing with other educational tools.

However, as globalization flattens the playing field, and countries leap to industrialization, cultural beliefs, natural resources, climate and geography have slowed the pace of development in many parts of the world. Poverty leads to malnutrition, homelessness, lack of education, and poor access to health care. Overcrowded cities and rural underdevelopment are other challenges that impact health in the various parts of the world. Moreover, epidemics of HIV, drug abuse and smoking addiction take a greater toll on the population. Yes, the world is flat, but the terrain is filled with mountains and valleys and local problems demand local solutions. And these local problems need to be explored and presented with a scholarly perspective. The *Textbook of Pulmonary and Critical Care Medicine* has successfully incorporated these sociodemographic factors into the subject matter.

The text is well-written and the chapters are carefully referenced with subjects found in all traditional pulmonary and critical care textbooks, e.g. airway diseases, interstitial lung disease, pleural disease, pulmonary neoplasia, pulmonary infection, sleep and critical care. There are several nontraditional sections as well that are practical and especially helpful to the practicing physician. These include a section on the symptom approach to lung disease, an overview of the pharmacologic agents used to treat lung disease, and a comprehensive review of methods in lung diagnosis from the simple history and physical examination to the latest complex tools of interventional pulmonology. The textbook is especially unique because of the abundance of illustrations, flow charts and tables. Their clarity and at times simplicity make them especially valuable for the novice. There are many radiographic and pathologic reproductions that are especially helpful.

The textbook also offers a unique exposure to the problems in many parts of the world. Tuberculosis, the "number one" treatable condition has been extensively covered; and special topics such as multi-drug resistance, directly observed therapy, TB prevention, nonpharmacologic approaches and extapulmonary tuberculosis are particularly relevant. Many countries are facing a growing burden of noncommunicable respiratory diseases. They have become the second leading cause of death after injuries, and their impact on indirect costs such as loss of work and home productivity is enormous. These problems are addressed and measures of prevention such as smoking cessation are included. Other special challenges including topics such as indoor and outdoor air pollution, climate change, poisoning with pesticides, snakebite toxicity, pulmonary manifestations of tropical infections and industrial accidents such as the tragedy seen in Bhopal, Madhya Pradesh, with methyl isocyanate, have been well covered.

What is most impressive about this textbook is how comprehensive and practical it is for the reader. Topics range from the history of respiratory medicine to the approach to end-of-life issues with critically ill patients. It is hard to think of a topic that is missing. While this textbook will have a special appeal and value to the physicians of the South-Asian continent, clinicians around the globe will benefit from Professor Jindal's extensive efforts.

Sidney Braman MD FCCP
Former President ACCP
Rhode Island Hospital, 593 Eddy Street
Providence, RI 02903 USA

Preface

It was merely a quarter of a century ago when the specialty of Pulmonary Medicine was factually recognized as an important division of Medicine. Until then, the lung diseases were generally dismissed as tuberculosis, or nondescriptive pneumonias and infections. Most of the nontuberculous lung diseases remained either undiagnosed or unknown. Of course, several stalwarts of the sixties and seventies had clearly identified this deficiency and made efforts to define the pulmonary problems and plan their solutions.

It was in 1989 that the first independent, postdoctoral DM Fellowship Program in Pulmonary Medicine was started at Chandigarh. Subsequently, the program was expanded to include the Critical Care as an essential component of the DM training. In addition, there were several postgraduate MD and/or diploma courses in tuberculosis and chest diseases, and/or respiratory diseases at different medical colleges. Unfortunately, most of the postgraduate programs lacked in their curricula especially for nontuberculous diseases and other systemic disorders. Moreover, the on-hand training in diagnostic and treatment modalities had been highly inadequate in the postgraduate courses. It is rather enigmatic that we still continue to lack the dedicated thoracic surgery courses and texts in the various countries.

The increased importance and scope of respiratory and critical care medicine had also necessitated the need to develop the indigenous teaching and training materials including the texts with incorporation of local problems and possible solutions. Undeniably, the science is the same all over the world, but the experiences are different. Excellent texts and reference materials on the subject are available for long which continues to guide the students, the teachers and the practicing physicians. In the present literature, quite a few textbooks of pulmonary medicine have been published and continue to remain available. Ours is one more attempt in this direction to add to the existing literature on lung diseases available worldwide. This book contains contributions by approximately hundred international esteemed pulmonary medicine consultants and teachers.

There are, however, a few important additions in the present textbook. It is fairly comprehensive with contributions from several internationally eminent authors. It includes the basic principles as well as the recent advances related to different subjects. We have also attempted to incorporate allied clinical sciences relevant to the practice of the pulmonologist. A classical example is the critical care which forms an integral component of pulmonary medicine. It also incorporates tuberculosis, other pulmonary infections, environmental and occupational medicines, sleep disorders and general systemic diseases affecting the respiratory system in one or the other way. Although the critical care is relevant to most of the medical and surgical specialties, the pulmonologists have a more vested interest than other specialists. Assisted respiration which forms the core of most critical care lies in the primary domain of pulmonologists.

We have taken care not to forget the need to push forward and meet the goals of excellence in health care. The real test of merit of a book lies in its readership by the students and adoption of its recommendations in clinical practice. Hopefully, the material in the text will benefit a diverse category of people including internists, general physicians, pulmonologists, pediatricians, intensivists, anesthesiologists and others who need to handle patients with respiratory diseases and critical care.

SK Jindal

Acknowledgments

I was greatly encouraged by my friends and colleagues in the department and elsewhere across the world. Almost none had refused my request to participate in this venture and provided best of his/her inputs. I am especially indebted to my Associate Editors and the Section Editors who have put extra efforts to make each section as all-inclusive. Drs PS Shankar, VK Vijayan, R Guleria, SK Chhabra, George D'Souza, and Sundeep Salvi had taken a lot of load on their shoulders. Most importantly, the international contributors had taken a lot of pains to enrich the book, purely for academic and scientific investments. In particular, I am thankful to Drs Om P Sharma, Irwin S Richards, Sidney S Braman, Robert McCaffree, Kalplatha K Guntupalli, Pravin Mathur, Ruby Pawankar, Peter Barnes, Daniel Banks and Suhail Raoof who have not only contributed themselves but also helped in getting the best from many others.

My faculty colleagues, Drs D Behera, Dheeraj, Ashutosh, Ritesh and Navneet, Senior Residents and Pulmonary-Fellows had remained a constant source of assistance. I greatly pay my sincerest appreciation to all of them. Ms Manju Aggarwal, my Secretary had done a remarkable job of refining and typing the manuscripts. I also owe a great deal of gratitude to my wife Umesh and children who have borne with my being busy and helping me in sorting out difficult matters.

Nothing could have been accomplished without the efficient editing and publishing by M/s Jaypee Brothers Medical Publishers (P) Ltd, Delhi who have done an excellent job. Shri Jitendar P Vij, CEO, had taken his personal interest in this publication. Dr Naren Aggarwal and Dr Richa Saxena deserve my special thanks for coordinating the process of publication.

2. **Anatomy and Architecture: A Clinical Perspective** **9**
SK Jindal
Lung Anatomy and Morphology 9; Architecture of Lung Parenchyma 12; Blood Supply of Lungs 13; Lymphatic Drainage 14; Nerve Supply 15

3. **Lung Development** **18**
Meenu Singh, Nidhi Anil, Amit Agarwal
Introduction 18

4. **Genomics of Lung Diseases** **24**
L Keith Scott
Introduction 24; Genomics and Disease 24; Genomic Nomenclature and Investigational Tools 25

SECTION 2: RESPIRATORY PHYSIOLOGY

SK Chhabra

5. **Applied Respiratory Physics** **35**
SK Jindal, VK Jindal
Introduction 35; State of Matter 35; Physical Properties of Gases 36; The Gas Laws 38; Gas Solution and Tension 39; Vapors 39; Expression of Gas Volumes and Pressures 40; Flow of Gases 40

6. **Respiratory Function and Mechanics** **43**
D Gupta, R Agarwal, Ashutosh N Aggarwal
Introduction 43; Ventilation 44; Pulmonary Circulation 48; Diffusion 50; Ventilation-perfusion ($\dot{V}/\dot{Q}$) Relationships 51; Control of Ventilation 52

7. **Gas and Fluid Exchange in the Lung** **54**
Marc Zelter
Gas Exchange 54; Dead Space and Alveolar Gas 56; Transfer of Gas across the Alveolar Capillary Membrane 57; Gas Transport to and from the Periphery 58; Ventilation Perfusion Ratio 60; Fluid, Solutes and Protein Exchange in the Lung 64; Clinical Implications 71; Measurement of Extravascular Lung Water 72

8. **Tissue Oxygenation** **74**
Puneet Malhotra, SK Jindal
Introduction 74; Oxygen Delivery (DO_2) 74; Oxygen Consumption (VO_2) 76; Assessment of Tissue Oxygenation 78; Recent Developments 79

9. **Respiratory Physiology in Specific Physiological States** **81**
Sunil K Chhabra, Mansi Gupta
Introduction 81; Exercise 81; Pregnancy 84; High Altitude 86; Deep Diving 88

10. Mechanisms of Dyspnea in Respiratory Diseases 93
Sunil K Chhabra, Ashima Anand
Introduction 93; Definitions 93; Perception: The Subjective Element in Dyspnea 94; Neural Pathways of Dyspnea 94; Pathophysiological Mechanisms of Dyspnea 97

11. Surfactant 107
Gyanendra Agrawal, SK Jindal
Introduction 107; Composition of Lung Surfactant 107; Functions of Lung Surfactant 109; Surfactant Metabolism and Surfactant Film Formation 110; Disorders of Surfactant Metabolism 112; Conclusion 115

12. Respiratory Defenses and Immunology 118
Padmavathi Ramaswamy, Padma Srikanth, Vijayalakshmi Thanasekaraan
Introduction 118; Particle Deposition in the Respiratory Tract 119; The Defense Mechanisms of Conducting Zone of the Airways 119; The Defense Mechanisms of Respiratory Zone of the Airways 124; Surfactant and Surfactant Protein A (Sp-A) 125; Respiratory Immune Mechanisms 126; Alveolar Macrophages 127; Impact of Bacteria and Viruses on Lung Immunology 130; HLA and Mycobacterial Diseases 131

SECTION 3: PHARMACOLOGICAL AGENTS

Nusrat Shafiq, Samir Malhotra

13. Antibacterial Drugs 135
Nusrat Shafiq, Samir Malhotra
Introduction 135; Beta-lactams 135

14. Antiviral Drugs 155
Nusrat Shafiq, Samir Malhotra
Introduction 155; Mechanism of Action of Antiviral Drugs 156

15. Antifungal Drugs 159
J Whig, Bharti Mahajan, Rajesh Mahajan
Introduction 159; Specific Issues 166; Clinical Implications of the Antifungal Drugs 166

16. Anti-inflammatory Agents for Asthma 171
Nusrat Shafiq, Samir Malhotra
Introduction 171; Corticosteroids 171; Dissociated Steroids 173; Mast Cell Stabilizers 176; Miscellaneous Drugs 177

17. Immunosuppressant Drugs 180
Nusrat Shafiq, Samir Malhotra
Introduction 180; Glucocorticoids 180; Calcineurin Inhibitors 181; Antiproliferative/ Antimetabolic Drugs 182; Immunosuppressive Cytotoxic Drugs 183; Miscellaneous Immunosuppressants 184

SECTION 4: SYMPTOM-APPROACH TO RESPIRATORY DISEASE

Richard S Irwin

18. Cough in the Adult 189
Scott E Kopec, Deirdre L Kathman, Richard S Irwin
Introduction 189; Epidemiology 189; Physiology 189; Pathophysiology 190; Benefits of Cough 190; Complications of Cough 190; Causes of Cough 191

19. Hemoptysis 204
Andrés F Sosa, J Mark Madison, Paulo J Oliveira
Introduction 204; Anatomy 205; Etiology and Pathogenesis 205; Treatment 213

20. Dyspnea **222**
J Mark Madison, Richard S Irwin
Introduction 222; Physiology 222; Positional and Nocturnal Dyspnea 224; Evaluating Acute Dyspnea 224; Evaluating Chronic Dyspnea 225; Treatment 226

21. Wheeze and Respiratory Disease **229**
J Mark Madison, Richard S Irwin
Introduction 229; Physiology of Wheeze 229; History and Physical Examination 229; Pulmonary Function Testing 230; Differential Diagnosis for Wheezing 232; Approach to the Diagnosis of Wheeze 235; Treatment 235

SECTION 5: RESPIRATORY DIAGNOSIS

SK Jindal

22. History and Physical Examination **241**
PR Gupta
Introduction 241; History Taking 241; History of Previous Diagnosis and Treatment 244, The Physical Examination 244

23. Microbiological Approach to Respiratory Infections **251**
Pallab Ray
Upper Respiratory Tract Infections 251; Lower Respiratory Tract Infections 255

24. Systematic Approach to Interpretation of Plain Chest Radiographs **264**
D Behera
Introduction 264; Radiology and Imaging 264

25. Pulmonary Imaging: Systematic Approach to Interpretation of Computed Tomography of the Chest **296**
Rubal Patel, Rakesh Shah, Sabiha Raoof, Suhail Raoof
Introduction 296; Technical Aspects 296; Normal Components of the Pulmonary Parenchyma 297; Normal Lung Components of the Airways 305; Normal Lung Component of the Pulmonary Vasculature 309; Tracheobronchial Diseases 311; Parenchymal Diseases 314; Mediastinal Diseases 324; Miscellaneous 326

26A. Pulmonary Function Testing **331**
Ashutosh N Aggarwal
Introduction 331; Spirometry 331; Peak Expiratory Flow 336; Static Lung Volumes 336; Diffusing Capacity of Lungs 338; Exercise Testing 340; Other Tests 342

26B. Respiratory Muscle Function **346**
Randeep Guleria
Introduction 346; Respiratory Muscles—Basic Physiology 347; Evaluation of Respiratory Muscle Function 348

27. Respiratory Disability and Preoperative Evaluation **358**
Gyanendra Agrawal, D Gupta
Introduction 358; Evaluation of Respiratory Disability 358; Clinical Methods of Evaluating Impairment 358; Disease-specific Impairment Assessment 360; Disability Evaluation 361; Preoperative Evaluation of Respiratory System 361; Postoperative Pulmonary Complications 363; Preoperative Evaluation 365; Recommended Approach 368; Optimizing the Chance of a Successful Outcome 369

28. Arterial Blood Gases and Acid Base Balance **373**
Vinaya S Karkhanis, Jyotsna M Joshi
Introduction 373; Physiology of Gas Exchange 373; Physiology of Acid Base Balance 374; Arterial Blood Gas Analysis 378; Arterial Blood Gas Interpretation 380; Interpretation of Arterial Blood Gas 384; Pitfalls in Arterial Blood Gas Interpretation 385; Examples 385

29. Nuclear Imaging in Pulmonary Medicine **387**
BR Mittal, Sunil HV
Introduction 387; Pulmonary Anatomy and Physiology 387; Investigations 387

30. Role of Cytology in Lung Lesions **399**
Arvind Rajwanshi, Nalini Gupta
Cytological Techniques in Respiratory Cytology 399; Aspirations 402; Imprint Cytology 403; Endoscopic Ultrasonography Guided FNA and Endobronchial Ultrasound FNA 403; Inflammatory Diseases of the Lung 403; Neoplastic Lesions of the Lung 407

31. Bronchoscopy **418**
R Narasimhan, AR Gayathri
Introduction 418; Types of Bronchoscopy 418; Patient Preparation and Anesthesia 419; Diagnostic Bronchoscopy—Accessories 419; Indications for Diagnostic Bronchoscopy 420; Diagnostic Procedures 424; Therapeutic Bronchoscopy 425; Electronavigation Bronchoscopy 426; Safety Factors in Bronchoscopy 426; Complications of Bronchoscopy 427

32. Interventional Bronchoscopy **429**
Praveen N Mathur, FD Sheski
Definition of Interventional Pulmonology 429; Advanced Imaging Bronchoscopy 430; Advanced Biopsy Techniques 431; Endoscopic Palliative Care 435; Nd:YAG Laser 435

33. Thoracoscopy **453**
C Ravindran, Jyothi E
Introduction 453; Medical Thoracoscopy 453; Surgical Thoracoscopy 459

SECTION 6: RESPIRATORY DISEASE IN THE DEVELOPING WORLD

SK Jindal

34. The Burden and Clinical Spectrum of Respiratory Diseases **463**
SK Jindal
Introduction 463; Respiratory Disease Burden 463; Clinical Spectrum of Respiratory Diseases in India 464; Tuberculosis 464; Non-tuberculous Respiratory Diseases 464; Future Scene of Pulmonary Medicine in India 469

35. Practical Approach to Lung Health **474**
Salah-Eddine Ottmani
Introduction 474; Demand of Care for and Management of Respiratory Patients 474; Objectives of the PAL Strategy 475; Components of the PAL Strategy 475; Adaptation of the PAL Strategy 477; Steps to Introduce the PAL Strategy in Countries 478; Results from Country Experiences 481

SECTION 7: TUBERCULOSIS

SK Jindal

36. Epidemiology of Pulmonary Tuberculosis **489**
VK Chadha
Introduction 489; National Dynamics of Tuberculosis 489; The Epidemic Curve of TB 492; Methods to Measure Epidemiology of TB and its Trends 493; India: A Case Study for Measuring 500; Epidemiological Situation and Trends 500; Global Trends of Tuberculosis 506

37. Risk Factors for Tuberculosis **511**
Parvaiz A Koul, Nargis K Bali
Introduction 511; Risk Factors of Developing Tuberculosis 511

38. Mycobacteria: An Overview **525**
Romica Latawa, Indu Verma
Introduction 525

39. Immunology and Pathogenesis **528**
Krishna K Singh, Indu Verma
Introduction 528; Mycobacterium Tuberculosis Infection and Overview of Immunopathogenesis 528; Immune Responses to Tuberculosis 530

40. Pulmonary Tuberculosis: Clinical Features and Diagnosis **539**
S Kashyap, Malay Sarkar
Introduction 539; Post Primary Pulmonary Tuberculosis 539; Symptoms and Signs 539; Tuberculosis in the Elderly 541; Miliary TB 541; HIV and TB 542; Pleural Effusion 542; Paradoxical Response 542; Physical Examinations 542; Diagnosis of Tuberculosis 543; Extrapulmonary Tuberculosis (EPTB) 549

41. Molecular Diagnosis of Tuberculosis **554**
Mamta Kalra, Indu Verma, Suman Laal
Introduction 554; Diagnosis of TB in Low-income Countries 554; Diagnosis of TB in High-income Countries 555; TB Diagnosis in HIV+ Individuals 556; Diagnosis of TB: Beyond Microscopy 556

42. Management of Tuberculosis **568**
D Behera
Chemotherapy of Tuberculosis 568; Rationale for Recommended Treatment 573; Regimens 573; Supervision of Chemotherapy 575

43. Antitubercular Drugs **578**
SK Katiyar, S Katiyar
Introduction 578; Isoniazid 579; Rifampicin 581; Streptomycin 583; Pyrazinamide 584; Ethambutol 585; Quinolones 586; Para-aminosalicylic Acid (PAS) 586; Ethionamide/Prothionamide 587; Cycloserine/Terizidone 587; Capreomycin 588; Thiacetazone 588; Group 5 Drugs 588; Clofazimine 589; Linezolid 589; Amoxicillin/Clavulanate 589; Imipenem/Cilastatin 589; Clarithromycin 589; High-dose Isoniazid 589

44. Historical and Non-pharmacological Management of Pulmonary Tuberculosis **594**
KB Gupta
Introduction 594; History 594; Ancient Drugs in the Treatment of Tuberculosis 595; Sanatorium Treatment 596; Surgery 598; Immunotherapy 599; Tuberculosis and Nutrition 600; Rehabilitation in Tuberculosis 602

45. Prevention of Tuberculosis **608**
Rajesh N Solanki, Ghanshyam B Borisagar, Jitendra A Sisodia
Introduction 608; Primordial Prevention 608; Primary Prevention 608; Secondary Prevention 612; Tertiary Prevention 615

46. BCG Vaccine **616**
PT James
Introduction 616; Complications of BCG Vaccination 619

47. Extrapulmonary Tuberculosis **622**
Ashok K Janmeja, Prasanta R Mohapatra
Introduction 622; Diagnosis 622; Lymph Node Tuberculosis 623; Pleural Effusion 625, Bone and Joint Tuberculosis 626; Central Nervous System Tuberculosis 628; Abdominal Tuberculosis 629; Genitourinary Tuberculosis 632; Skin Tuberculosis 633; Disseminated Miliary Tuberculosis 634; Pericardial Tuberculosis 636; Hepatic Tuberculosis 637

48. Multidrug-resistant Tuberculosis **641**
Surendra K Sharma, Ninoo George
Introduction 641; Epidemiology 641; Definition 642; Causes of Drug Resistance 642; Diagnosis of Drug-resistant TB 643; Management 644; Role of Immunotherapy 647; Resective Thoracic Surgery 648, Nutritional Support 648; Special Situations 648; Prevention of Nosocomial Transmission of MDR-TB 649; Financial Burden of MDR-TB 650; Cure Rates in MDR-TB and XDR-TB 651

49. Revised National Tuberculosis Control Programme in India—DOTS and DOTS Plus **656**
D Behera
Introduction 656; Revised National Tuberculosis Control Programme 657; Diagnosis of Pulmonary Tuberculosis 662; Ziehl-Neelsen Staining Procedure 663; Treatment 668; Management of Pediatric Tuberculosis Under RNTCP 674; Management of Extrapulmonary Tuberculosis 676; Management of Patients with HIV Infection and Tuberculosis 677; Recording and Reporting 680; Supervision, Monitoring and Evaluation 683; Training 686; Special Initiatives 686; Multidrug-resistant Tuberculosis and DOTS Plus 691; Infection Control and Hospital Waste Management 692; Information, Education and Communication 693

50. Treatment of Tuberculosis in Special Situations **695**
Rajendra Prasad
Introduction 695; Pharmacokinetics of Antitubercular Drugs 695; Treatment of Tuberculosis in Pregnancy and Lactation 696; Treatment of Tuberculosis in 696; Renal Insufficiency 696; Treatment of Tuberculosis in Liver Disease 698

51. Tuberculosis and Human Immunodeficiency Virus Infection **701**
SK Jindal
Introduction 701; Epidemiology 701; Pathogenesis 702; Clinical Effects of HIV on Tuberculosis 702; Diagnosis 704; Management 704

52. Nontuberculous Mycobacterial Infections **710**
PS Shankar, SK Jindal
Introduction 710

SECTION 8: RESPIRATORY INFECTIONS

SK Jindal

53. Community-acquired Pneumonia **719**
Charles Feldman, Ronald Anderson
Introduction 719; Epidemiology 719; Microbial Etiology of Community-Acquired Pneumonia 720; Risk Factors for Community-acquired 721; Pneumonia 721; Pathogenesis of Cap with Particular 722; Reference to the *Pneumococcus* 722; Diagnostic Testing 723; Prognosis 724; Treatment of Community-acquired 726; Pneumonia 726; Prevention of Infection—Vaccination 727

54. Pulmonary Fungal Infections **734**
Arunaloke Chakrabarti
Introduction 734; Epidemiology 734; Agents Responsible 735

55. Pulmonary Mycetoma **747**
Alladi Mohan, B Vijayalakshmi Devi, Abha Chandra
Introduction 747; Pathogenesis 747; Pathology 747; Clinical Presentation 748; Diagnosis 749; Treatment 753; Prognostic Factors 754; Overall Mortality 754

56. Nosocomial Pneumonia **757**
Vishwanath Gella, SK Jindal
Introduction 757; Pathogenesis 757; Diagnosis 757; Risk Stratification of Patients with VAP 759; Treatment 760; Prevention of HAP and VAP 762

57. Viral Pneumonias **765**
Arjun Srinivasan, Ritesh Agarwal
Introduction 765; Respiratory Viruses 765; Presenting Features 766; Risk Factors and Features of Severe Disease 771; Respiratory Protection for Health 772; Care Professionals 772

58. Pulmonary Manifestations of Human Immunodeficiency Virus (HIV) Infection **776**
Zarir F Udwadia
Introduction 776; *Pneumocystis Jiroveci* Pneumonia (PJP) 777; Community-acquired Pneumonias (CAPs) 778

59. Lung Abscess **780**
C Ravindran, Jyothi E
Definition 780; Epidemiology 780; Classification 780; Etiology 781; Pathogenesis 781; Pathology 782; Clinical Features 783; Complications 785; Treatment 786; Prognosis 787

60. Bronchiectasis and Cystic Fibrosis **790**
David Honeybourne
Bronchiectasis 790; Cystic Fibrosis 795

61. Rare Respiratory Infections **801**
Mohankumar Thekkinkattil, S Arulmozhi
Introduction 801; Viral Infections 801; Bacterial Infections 801; Rare Forms of Tuberculous Infections 802; Chlamydial Infections 802; Parasitic Infection 803; Zoonotic Bacterial Pneumonias 804

62. Parasitic Lung Diseases **806**
VK Vijayan
Introduction 806

63. Anaerobic Bacterial Infections of the Lungs and the Pleura **820**
Ashok Shah, Chandramani Panjabi
Introduction 820; Historical Note 820; Pathophysiology 821; Natural History and Clinical Classification 822; Anaerobes and Upper Respiratory Syndromes 823; Incidence 823; Microbiology 824; Clinical Features 824; Laboratory Diagnosis 825; Radiological Manifestations 827; Treatment 827; Prognosis 828

SECTION 9: ASTHMA

SK Jindal

64. Bronchial Asthma—Epidemiology **835**
SK Jindal
Introduction 835; Definition 835; Epidemiology 835; Economic Burden 835; Epidemiological Differences 836; Factors Influencing Prevalence of Asthma 836

65. Allergic Rhinitis, Asthma and Comorbidities **840**
Ruby Pawankar, Satoko Kimura, Sachiko Mori, Yukiko Yokoyama
Introduction 840

66. Asthma Diagnosis **847**
Liesel D'silva, Parameswaran Nair
Introduction 847; Clinical Diagnosis 847; Tests for Diagnosis and Monitoring 847; Diagnostic Challenges 855

67. Airway Inflammation and Remodeling **866**
Ruby Pawankar, Shu Hashimoto, Bassam Mahboub, Chika Ozu
Introduction 866; Chronic Inflammation in AR and Asthma 867; Remodeling in Asthma 870

68. Control and Management of Stable Asthma **876**
Sidney S Braman, David Lee
Introduction 876; The Goals of Asthma Treatment 876; Essential Components of Asthma Care 877; Treatment Protocols for Asthma 885; Asthma Control in Developing Countries 887

69. Management of Severe Asthma **893**
Liesel D'silva, Parameswaran Nair
Introduction 893; Development of Severe Asthma 893; Phenotypes in Severe Asthma 894; Managing Severe Asthma using Airway Inflammatory 902; Monitoring a Patient with Difficult Asthma 903

70. Immunotherapy and Immunomodulators for Allergic Rhinitis and Asthma **909**
Ruby Pawankar, Giovanni Passalacqua
Introduction 909; Subcutaneous Immunotherapy (SCIT) 909; The Sublingual Route 911; Future Developments of SIT 913

71. Allergen Desensitization **918**
Vikram Jaggi
Introduction 918; Definition 918; Historical Background 918; Mechanisms of Allergen Immunotherapy 919; Future Directions 923

72. Bronchodilators **926**
Samir Malhotra, Nusrat Shafiq
Introduction 926; Beta-2 Adrenergic Agonists 926; Methylxanthines (Xanthines) 930; Anticholinergic Agents 931

73. Patient Education in Asthma **934**
Bharat Bhushan Sharma, Virendra Singh
Introduction 934; Goals of Asthma Education Programs 934; Benefits of Asthma Education Programs 935; Methods and Settings 935; Asthma Education Program Components 936; Patient Education: Problems 936

74. Childhood Asthma **939**
Meenu Singh
Epidemiology 939; Definition 940; Pathophysiology 940; Diagnosis 941

75. Allergic Bronchopulmonary Aspergillosis **947**
Ritesh Agarwal
Introduction 947; Epidemiology of ABPA 948; Pathogenesis of Abpa 949; Pathology of ABPA 949

SECTION 10: CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Sundeep Salvi

76. Chronic Obstructive Pulmonary Disease: The Neglected Epidemic **971**
Sundeep Salvi
Mortality Due to Chronic Obstructive 971; Pulmonary Disease 971; Morbidity Due to COPD 971; The Economic Burden of COPD 971; Risk Factors for COPD 971, Primary and Secondary Prevention of COPD 973

77. Health and Economic Burden of Chronic Obstructive Pulmonary Disease **975**
Monica Barne, Sundeep Salvi
Introduction 975; Mortality Due to COPD 975; Prevalence of COPD 979; Disability-adjusted Life Years Due to COPD 983; Economic Burden of COPD 984

78. Risk Factors for Chronic Obstructive Pulmonary Disease **987**
Sneha Limaye, Sundeep Salvi
Introduction 987; Tobacco Smoking 987; Indoor Air Pollution as a Risk Factor for COPD 988; Outdoor Air Pollution and COPD 989; COPD Associated with Occupational Exposures 989; Copd Associated with Pulmonary Tuberculosis 989; Chronic Asthma as a Risk Factor for COPD 990; Genetic Factors 991; Socioeconomic Status 991

79. Pathophysiology of Chronic Obstructive Pulmonary Disease **993**
Bill Brashier, Sundeep Salvi
Introduction 993

80. Pulmonary Function Testing in Chronic Obstructive Pulmonary Disease **1015**
Tavpritesh Sethi, Anurag Agrawal
History and Evolution 1015; The Clinical Need for Pulmonary Function Tests 1016; Physiological Principles 1016; Clinical Applications 1019; Measuring Small Airway Disease: Impulse Oscillometry 1022; Other Tests 1023; The Future 1025

81. Systemic Manifestations and Comorbidities **1027**
SK Jindal, PS Shankar
Introduction 1027; Pathogenesis 1027; Systemic Manifestations 1028; Therapeutic Considerations 1030

82. Role of Infections in Chronic Obstructive Pulmonary Disease **1033**
Suruchi Mandrekar, Sundeep Salvi
Introduction 1033; Do Bacteria Cause/Initiate COPD? 1033

83. Treatment of Chronic Obstructive Pulmonary Disease **1041**
Peter J Barnes
Introduction 1041; Risk Factors and their Prevention 1041; Other Drug Therapies 1049; Non-pharmacological Treatments 1050; Managing Chronic Disease 1051; Treatment of Acute Exacerbations 1051; Treatment of Cor Pulmonale 1052; Future Therapies 1052

84. Acute Exacerbations of Chronic Obstructive Pulmonary Disease **1056**
Raja Dhar, AG Ghoshal
Introduction 1056; COPD Exacerbation 1056; Assisted Ventilation 1061

85. Long-term Oxygen Therapy **1065**
R Agarwal, SK Jindal
Selection of Patients 1065; Benefits 1066; Perspectives of Domiciliary Oxygen Use in India 1071

86. Patient Education in Chronic Obstructive Pulmonary Disease **1073**
Tushar Sahasrabudhe
Introduction 1073; Education about the Disease 1073; Education to Help Reduce COPD 1075; Exacerbations 1075; Education for Improving Baseline Lung 1075; Function 1075; Pulmonary Rehabilitation 1076; Education and Discussion on Daily Life 1077; Issues 1077; Discussion on Special Issues 1077; Prevention of COPD 1078; Early Detection of COPD 1078

87. End-of-life Communication and Palliative Care in Advanced COPD **1080**
Sujeet Rajan
Introduction 1080; Advanced Terminal COPD 1080; Prognosis of Advanced COPD 1080; Good Death in COPD: Implications 1081; Principles of End-of-life Communication in COPD 1082

88. Smoking/Tobacco Control **1085**
Virendra Singh, Bharat Bhushan Sharma
Introduction 1085; Tobacco Smoking 1085; Smoking Control Interventions 1089

89. Pulmonary Rehabilitation **1097**
Rachael A Evans, Roger S Goldstein
Symptoms and Disability Associated with Chronic Obstructive Pulmonary Disease 1097; The Role and Definition of Pulmonary 1098; Rehabilitation 1098; Future Work 1106

90. Upper and Central Airway Obstruction **1109**
VR Pattabhi Raman
Introduction 1109; Acute UAO 1112; Chronic UAO 1113; Therapeutic Considerations 1120

91. Bronchiolar and Bullous Lung Diseases **1123**
Gyanendra Agrawal, Dheeraj Gupta
Introduction 1123; Bronchiolitis 1123; Bullous Disease of the Lung 1132

92. Immunomodulators in Respiratory Diseases **1138**
Agam Vora
Introduction 1138

SECTION 11: INTERSTITIAL LUNG DISEASE

Dheeraj Gupta

93. Approach to Diagnosis of Interstitial Lung Disease **1145**
Dheeraj Gupta
Introduction 1145; Etiology and Classification 1145; Epidemiology 1147; Pathology 1147; Pathogenesis 1148; Diagnostic Approach 1149; Management 1151; Acute Exacerbation of ILD 1155; Prognosis 1155

94. Pathology of Interstitial Lung Disease **1160**
Amanjit Bal, Kusum Joshi
Idiopathic Interstitial Pneumonia 1160; Idiopathic Bronchiolocentric Interstitial Pneumonia (BRIP)/Airway Centered Interstitial Fibrosis 1167; Drug Induced Interstitial 1168; Lung Disease (DIILD) 1168; Connective Tissue Disorder Associated Interstitial Lung Disease 1169; Hypersensitivity Pneumonitis (HP) 1170; Lymphangioleiomyomatosis (LAM) 1170; Pulmonary Langerhans Cell Histiocytosis (LCH) 1171

95. Idiopathic Interstitial Pneumonias **1174**
H Shigemitsu, Ngozi Orjioke
Introduction 1174; Epidemiology 1174; Classification 1174; Clinical Features 1174; Histological Features 1176; Treatment 1177; Idiopathic Pulmonary Fibrosis (IPF) 1177; Nonspecific Interstitial Pneumonias (NSIP) 1180; Desquamative Interstitial Pneumonia (DIP) 1181; Respiratory Bronchiolitis-associated Interstitial Lung Disease (RB-ILD) 1182; Cryptogenic Organizing Pneumonia (COP) 1182; Acute Interstitial Pneumonia (AIP) 1184; Lymphoid Interstitial Pneumonia (LIP) 1185

96. Sarcoidosis **1188**
Dheeraj Gupta, Om P Sharma
Introduction 1188; History and Epidemiology 1188; Risk Factors 1189; Pathogenesis and Immunology 1191; Pathology 1192; Clinical Features 1192; Diagnosis 1199; The Tuberculosis Enigma 1201; Treatment 1202; Prognosis and Mortality 1207; Future Directions 1208

97. Pulmonary Eosinophilic Disorders **1217**
Subhash Varma, Aditya Jindal
Introduction 1217; Pulmonary Eosinophilic Disorders 1218; Approach to Diagnosis and Conclusion 1225

98. Infiltrative and Deposition Diseases **1229**
Pralay Sarkar, Arunabh Talwar
Introduction 1229; Pulmonary Amyloidosis 1229; Lysosomal Storage Disorders 1236

SECTION 12: DISORDERS DUE TO ENVIRONMENTAL AND CLIMATE FACTORS

SK Jindal

99. Outdoor Air Pollution and Respiratory Health **1255**
Sara Maio, Sandra Baldacci, Marzia Simoni, Fabio Cibella, Giovanni Viegi
Introduction 1255; Outdoor Air Pollution Effects 1255

100. Indoor Air Pollution and Respiratory Health 1266
Marzia Simoni, Sara Maio, Sandra Baldacci, Fabio Cibella, Giovanni Viegi
Introduction 1266; Prevention and Conclusion 1272

101. Environmental Risk Factors for Respiratory Disease 1275
Kalpana Balakrishnan
Introduction 1275; Environmental Risk Factors 1275

102. Climate Change and Lung Disease—With Special Focus on Developing Countries 1288
Kin Bong Hubert Lam, Jon G Ayres
Climate Change: An Introduction 1288; Future Projections of Climate Change 1289; Impact of Climate Change on Health 1289; Climate Change and Lung Disease 1289; Synergy between Air Pollution and Temperature 1292

103. High Altitude Problems 1296
Ajay Handa
Introduction 1296

104. Aviation and Space Travel 1301
Ajay Handa
Air Travel 1301; Space Travel 1303

INTERSTITIAL LUNG DISEASE

Dheeraj Gupta

93

Approach to Diagnosis of Interstitial Lung Disease

Dheeraj Gupta

INTRODUCTION

Diffuse Interstitial Lung Disease (ILD) encompasses a group of disorders of diverse etiologies with the common feature of generalized involvement of the lung interstitium. It is a heterogeneous group of diseases and includes over 200 different diseases, which in spite of their heterogenous nature have several common clinical, radiological and histological manifestations. The presenting symptoms of cough and dyspnea are nonspecific and the diagnosis is often delayed unless the examining physician has a high level of suspicion. Diagnosis comes from a thoughtful history/physical examination coupled with specific laboratory and radiological investigations. The etiology may be further clarified by lung biopsy, however it is not essential. Depending on the etiology, therapy may include immunosuppression, trigger avoidance or observation. The prognosis is closely tied to the etiology. Overall, early diagnosis is critical for best patient outcomes and is dependent on physician's awareness of this often deadly disease.

ETIOLOGY AND CLASSIFICATION

The classification of ILD is confusing and still evolving. Several terminologies and classifications have been used to describe the same clinicopathological disease. ILD is broadly grouped as (a) Primary, when the cause is unknown, and (b) Secondary, when there is an identifiable disease responsible for the interstitial involvement (Table 93.1).

Primary ILD

Primary ILD is idiopathic in origin. No secondary cause or association is identifiable. It was also known in the past as cryptogenic fibrosing alveolitis or Idiopathic Pulmonary Fibrosis (IPF) or "lone IPF". This group of Idiopathic Interstitial Pneumonias (IIP) based on clinicoradiological and pathological features, is now classified into seven distinct types:[1] UIP, DIP, LIP, NSIP, AIP or DAD, and COP. Some of these IIPs such as the DIP, NSIP and RBILD are characteristically associated with the smoking history (See Chapter 95).

Secondary ILDs

Most forms of secondary ILDs have either a known etiological cause or an association with another disease of known (or unknown) etiology (Table 93.1). An ILD secondary to another illness factually represents the pulmonary involvement of the primary disease than a separate entity. There are more than 200 conditions/ exposures known to be associated with ILD. The American Thoracic Society (ATS) and the European Respiratory Society (ERS) International Consensus Statement on ILD categorized ILDs into three broad groups: (1) DPLD with known cause [e.g. connective tissue disease (CTD), hypersensitivity pneumonia, toxins, infections, inherited, malignancy, pneumoconiosis]; (2) Granulomatous DPLD (e.g. sarcoidosis) and (3) Other Diffuse Parenchymal Lung Diseases (DPLDs) [e.g. lymphangioleiomyomatosis (LAM), histiocytosis, esosinophilic lung diseases, etc.] Unfortunately, the etiology of a given ILD more often falls into the idiopathic

TABLE 93.1: Important causes of interstitial lung disease

I. Primary or Idiopathic Interstitial Pneumonias
  1. Usual Interstitial Pneumonia (UIP), i.e. Idiopathic Pulmonary Fibrosis
  2. Nonspecific Interstitial Pneumonia (NSIP)
  3. Cryptogenic Organizing Pneumonia (COP)
  4. Respiratory Bronchiolitis associated ILD (RBILD)
  5. Acute Interstitial Pneumonia (AIP) / Diffuse Alveolar Damage (DAD)
  6. Desquamative Interstitial Pneumonia (DIP)
  7. Lymphocytic Interstitial Pneumonia (LIP)

II. Secondary
  A. *Known Causes*
    1. Infections
      - Tuberculosis
      - Bacterial
      - Fungal
      - Parasitic
      - Viral
    2. *Noninfectious causes*
      - Hypersensitivity pneumonitis
      - Pneumoconiosis
      - Drug induced
      - Radiation induced
      - Malignancies
      - Systemic vasculitides
  B. *Association with Diseases of Inflammatory or Unknown Etiology*
    1. *Sarcoidosis*
    2. *Connective tissue disorders*
      - Systemic sclerosis
      - Rheumatoid arthritis
      - Polymyositis/dermatomyositis
      - Systemic lupus erythematosus
    3. *Chronic eosinophilic pneumonia*
    4. *Miscellaneous*
      - Histiocytosis
      - Eosinophilic granuloma
      - Lymphangioleiomyomatosis
      - Tuberous sclerosis

category. Even in cases of ILD with a defined etiology, the mechanisms of lung injury and fibrosis are largely undefined.

Connective Tissue Diseases

The most important association of ILD is seen with different connective tissue disorders (CTDs). Pulmonary Fibrosis is most prevalent in Systemic Sclerosis (SSc-PF), forming part of the American Rheumatism Association minor diagnostic criteria for SSc.[2] Clinically significant pulmonary fibrosis occurs in approximately 30% of patients with SSc and polymyositis/dermatomyositis (PM/DM), 10% with Sjögren's syndrome (SS), and in less than 5% with Systemic Lupus Erythematosus (SLE) or Rheumatoid Arthritis (RA).[3] Studies of lung function and High Resolution Computed Tomography (HRCT) scanning suggest a much higher prevalence of subclinical disease in all of these disorders.[4-7] Ankylosing Spondylitis (AS) is frequently associated with limited nonspecific HRCT abnormalities, but clinically significant upper zone fibrobullous disease is relatively uncommon.[8] There is a great degree of overlap between idiopathic pulmonary fibrosis and fibrosis associated with different CTDs.

Occupational and Environmental Exposures

Occupational exposure to different inorganic and metal dusts is another important cause. Silica dust causes progressive fibrosis, massive progressive fibrosis can occur in a much shorter period of a few weeks to a few months in case of a heavy exposure. Asbestosis and anthracosis are also associated with pulmonary fibrosis. Inhalation of toxic gases and fumes, such as methyl isocyanate and nitrogen dioxide can cause interstitial involvement. In view of a shorter exposure, it is generally self-limiting, but chronic pulmonary involvement from inhalational exposure is also possible.

Drugs (See Chapter 114)

Several drugs are known to cause ILD. Pneumotox® (www.pneumotox.com) provides free and updated information on drug-induced respiratory disease. Drugs and drug classes which more often cause ILD include amiodarone, chemo agents [bleomycin, busulfan, chlorambucil, cyclophosphamide, gemcitabine, imatinib, methotrexate, mitomycin C, nitrosoureas (BCNU, CCNU and newer nitrosoureas), rituximab, trastuzumab and taxanes], disease-modifying anti-rheumatic drugs (methotrexate, anti-TNF-alpha antibody therapy), interferon, minocycline, nitrofurantoin, nonsteroidal anti-inflammatory drugs (NSAIDs), and rapamycin.[9] Drugs given by almost any route of administration [oral, parenteral, inhaled, topical (ophthalmic, dermal, intranasal), intrathecal, intracavitary and intra-arterial] can cause ILD. However, the vast majority of cases results from oral or parenteral administration of drugs. The incidence rate of drug-induced ILD varies with the specific drug and among studies and is between 1/100,000 and 1/5,000 treatment courses for nitrofurantoin, to 1 to 5% of patients exposed to the regular doses of amiodarone long term, 17 to 36% of patients treated with rapamycin and congeners[10] and greater than 30% in patients exposed to high-dose amiodarone (>1,200 mg/day).[11]

Radiation

Radiation administered for thoracic malignancies, especially when used in a higher dose, is another iatrogenic cause of ILD.[12] Radiation can induce both pulmonary and mediastinal fibrosis. Radiation lung injury can manifest during weeks, months or years after radiation therapy for lung cancer, breast carcinoma, Hodgkin's or non-Hodgkin's lymphomas, or following total body irradiation in recipients of bone marrow or stem cell transplant. Radiation induced changes may involve the pleura, heart, pulmonary veins, mediastinum, lymphatic vessels and nerves in addition to the lung, creating manifold possibilities and patterns of involvement.

Hypersensitivity Pneumonias (See Chapter 112)

Hypersensitivity pneumonias (extrinsic allergic alveolitis) of acute, subacute or chronic onset, which occur on exposure to known environmental or occupational antigens, include farmer's lung, byssinosis, air-conditioner lung, bird-fancier's disease and mushroom picker's disease. They may also occur in individuals working with different chemicals, drugs, pharmaceutical agents and laboratory animals. This is especially so in the industrial workers engaged in the manufacturing/processing of rubber foam, azo-dyes, tetracyclines, ampicillin, antihypertensive drugs and others.[13]

EPIDEMIOLOGY

Although the exact incidence and prevalence of ILD is not known, patients with this disease comprise about 15% of a pulmonary physician's practice.[14,15] Mortality from cryptogenic fibrosing alveolitis continues to increase in many countries.[16] In India, this was earlier considered to be a rare disease. In 1979, Jindal et al. published their data on 61 cases of DPLD seen over a period of five years.[17] However, the scenario is different now and the disease is no longer rare or uncommon. Recently the same center published data on 76 patients with IPF diagnosed over a 16-month period showing a definite increase in the frequency of diagnosis.[18] A number of other publications from India have described various aspects of the disease.[19-31] The increase in the number of studies from India may be a true reflection of the increase in the incidence or may be apparent because of increased awareness of the condition or due to better availability of diagnostic facilities like HRCT and fibreoptic bronchoscopy.

Globally, also the incidence and prevalence of ILD is unclear, as it is often found incidentally and can be the result of innumerable insults. Idiopathic pulmonary fibrosis, is the most common and best studied ILD. The prevalence of this disease was studied in Bernalillo County, New Mexico, and was estimated to be 13.2 to 20.2 per 100,000, with an annual incidence of 7.4 to 10.7 per 100,000 cases per year.[15] Since IPF accounts for 60% of the ILD cases, one can estimate the true incidence of ILD in the general population is much greater.[15] Furthermore, the prevalence of IPF in individuals older than 75 years of age has been estimated to be as high as 175 per 100,000.[15] This is of importance given that two-thirds of patients with IPF are over 60 years of age at diagnosis and globally the population is ageing, ILD will be encountered with increasing frequency.[32] In a recent population-based study from Olmsted County, Minnesota, from 1997 to 2005, the age- and sex-adjusted incidence was 8.8/100,000 and 17.4/100,000 person-years, using narrow or broad criteria respectively. The age-adjusted incidence was higher in men than in women, and among patients aged 70 to 79 years and had shown a significant decline during the study period.[33]

PATHOLOGY

As is implied in the name the primary site of pathology is in the pulmonary interstitium. The diverse etiologies lead to pulmonary inflammation and/or fibrosis as the final common pathways to lung damage. Hence, the ILDs are often referred to collectively as "pulmonary fibrosis." The normal pulmonary interstitium comprises of the anatomical space between the alveolar and the capillary basement membranes. In a normal lung, this space is occupied by a single cell layer, only 10 microns in width, allowing passive diffusion of oxygen between the alveolus and blood in the capillaries. It also contains mesenchymal and connective tissue cells, and extracellular matrix composed of collagen, elastin and proteoglycans. Characteristically, there is cellular infiltration and thickening of pulmonary interstitium and of alveolar walls, as well as spillage of mononuclear cells in the alveolar lumen. The cellular exudate comprises primarily of alveolar macrophages, but lymphocytes, neutrophils, eosinophils and plasma cells are also present.

Although the total collagen component of lungs remains normal, the ratio of type I to type III collagen is increased. The interstitial involvement progressively encroaches the alveolar spaces, the terminal bronchioles and also the overlying pleura. It is for this reason the ILDs are also referred to as "Diffuse Parenchymal Lung Diseases" (DPLDs). The advanced-stage disease is characterized by extensive fibrosis, obliteration of the lumen of alveoli and formation of multiple cysts, also called as the honeycomb lung. The ILDs are distinct from diseases predominantly affecting the airways and blood vessels.

PATHOGENESIS

There is no clear understanding of disease-pathogenesis. Chronic inflammation, recurrent epithelial injury and impaired wound repair are some of the possible reasons of pulmonary fibrosis.[34] Several new mechanisms of pulmonary fibrosis have evolved in the last decade. Pulmonary fibrosis is considered to result from an aberrant defense reaction with failure of mechanisms which are normally responsible for repair. It is now recognized that there is persistence and/or repetitive injury responsible for inflammation followed by recruitment of a host of inflammatory cells.[35]

Recently an interesting perspective has proposed that ILD (IPF) should be considered as a neoproliferative disorder of the lung. Genetic alterations, response to growth and inhibitory signals, resistance to apoptosis, myofibroblast origin and behavior, altered cellular communications, and intracellular signaling pathways are all fundamental pathogenic hallmarks of both IPF and cancer and IPF is associated with a poor prognosis, like the cancers.[36]

Several pathobiological processes have been identified or proposed, some of which have been outlined below (Fig. 93.1), a detailed account being out of preview of this chapter.

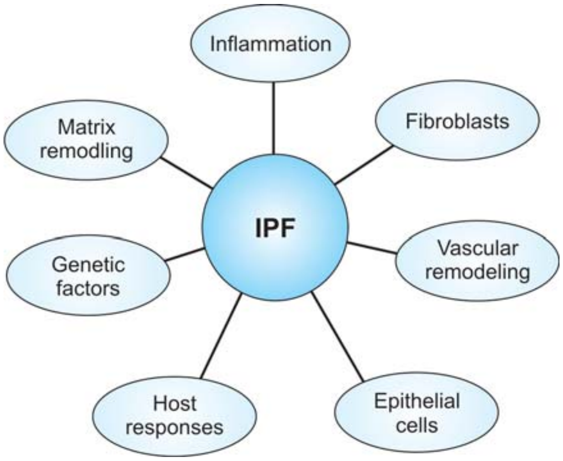

Fig. 93.1: Proposed mechanisms for development of pulmonary fibrosis

Inflammatory Hypothesis

Inflammation as the central mechanism causing IPF was largely derived from the observation that bronchoalveolar lavage fluid from patients with IPF had increased numbers of inflammatory cells (mostly neutrophils and eosinophils) relative to normal individuals. Therapies were therefore directed at abrogating inflammation with corticosteroids. However, lack of response to corticosteroids has lead to the belief that inflammation may be a result, rather than a cause of the fibrosis. This was supported by the studies showing increased levels of the CXC chemokine IL-8/CXCL8, a potent chemotactic cytokine for neutrophils in lung tissue.[37]

Vascular Hypothesis

Increased angiogenesis has been suggested to play an important role in the progression of pulmonary fibrosis in both animal models and clinical specimens.[38,39] This increased angiogenic activity has been attributed to an imbalance of pro-angiogenic chemokines (IL-8, ENA-78) and anti-angiogenic CXC chemokines (IP-10/CXCL10).[40,41] In contrast, recent reports have shown decreased expression of Vascular Endothelial Growth Factor (VEGF) and endothelial cell proliferation in IPF.[40-42] It is likely that angiogenesis may be enhanced in the earlier stages of the development of UIP, while there is a loss of blood vessels in the more advanced stages. Pulmonary hypertension is becoming recognized as an important clinical component of progressive IPF in some patients.[21,43]

Alveolar Epithelial Cells

Abnormalities in alveolar type II cell injury and repair may be a critical feature in the pathogenesis of pulmonary fibrosis. Ultrastructural studies have demonstrated alveolar type II cell injury and apoptosis in lung biopsies from IPF patients. Studies have demonstrated increased expression of proapoptotic proteins in alveolar epithelial cells and in Broncho-alveolar Lavage (BAL) from IPF patients. More recent data have suggested that there is increased oxidative stress in alveolar epithelium in IPF patients.[44-49]

Matrix Remodeling

There is an imbalance between the production and degradation of extracellular matrix, which leads to excessive production of extracellular matrix molecules including collagens, tenascin, proteoglycans and glycosaminoglycans.[50] TGF-beta promotes matrix production and inhibits inhibitors of matrix degradation (TIMPs) and thus could be a key mediator in this process.[51,52]

Fibroblast Activation and Dysfunction

A variety of growth factors that influence fibroblast and myofibroblast functions have been shown to be produced in the lung tissue of IPF patients. These include Th2 cytokines (IL-4, IL-5 and IL-13), growth factors such as TGF-β, IGF-1[53], PDGF A or B and CTGF.[54] Also the fibroblasts in IPF may have unique phenotype that can have different growth rates.[55,56] Recent studies suggest that myofibroblasts may also have an important role in mediating lung fibrosis.[46,57,58]

DIAGNOSTIC APPROACH

Diagnosis of ILD is generally suspected on history and clinical examination. However, a comprehensive evaluation is required to narrow down the possible predisposing factor in the secondary ILD or to assign it to one of the known categories of idiopathic varieties. This exercise is important as there are important treatment and prognostic implications to a proper diagnosis. The final diagnosis of ILDs essentially rest on the evaluation of ***C***linical, ***R***adiological and ***P***athological data in unison and is also referred to as ***C-R-P*** diagnosis. In approaching the ILD several actions are required, which include:

- A methodical history to include demographics, family history, and occupational/environmental exposures
- Physical examination
- Chest radiographs
- High resolution computed tomographic scans
- Blood tests
- Fiberoptic bronchoscopy with BAL or transbronchial lung biopsies (selected patients)
- Surgical lung biopsy (selected patients)

Clinical History

The clinical signs and symptoms of ILD are generally not specific to a diagnosis of ILD. Individuals present with progressive dyspnea on exertion and dry cough. Symptoms are usually progressive. Since two-thirds of patients with ILD are over 60 years of age at diagnosis, the initial symptoms may be attributed to cardiac disease, deconditioning or advancing age, thus delaying the ultimate diagnosis and treatment.[26] A thoughtful assessment of the course and progression of the illness (weeks, months, years) provides some suggestions regarding etiology. A long history over many years is a good hint for idiopathic pulmonary fibrosis. Clinical data may be used to predict a diagnosis of IPF over other IIPs.[59] A patient with a much more fulminant presentation is suggestive of COP or AIP. Occasionally, additional symptoms, may suggest a potential etiology for the ILD (Table 93.2). Connective tissue disease-associated ILD (CT-ILD) often presents in previously diagnosed CTD, although ILD may predate other manifestations of CTD. In these patients, specific symptoms related to various CTDs provide a critical clue to the etiology of the lung disease. An increased incidence of ILD has been noted in certain families. These cases of “familial idiopathic pulmonary fibrosis” are thought to account for less than 3% of all cases and may be associated with a defect in surfactant protein C.[60] Careful history of drug and tobacco use is also important.[61,62]

Physical Examination

Physical examination is helpful in suggesting interstitial involvement, but rarely it leads to a specific diagnosis (Table 93.2). The bibasal dry, end-inspiratory “velcro” crackles are quite characteristically heard in most patients of IPF. These crackles are attributed to the snap opening up of collapsed alveoli when equalization of pressure occurs between the alveolar spaces and the proximal bronchiole during inspiration.[1,63] Finger-clubbing is present in about one-third of patients. Hypertrophic osteoarthropathy is rarely seen. Cyanosis is generally absent at rest but desaturation occurs and cyanosis appears after even mild exercise. Cyanosis may be present even at rest in an advanced disease. Physical examination of the chest may reveal tachypnea, reduced chest expansion and intercostal retractions. Breath sounds are vesicular and quite distinct. Bronchovesicular or bronchial breathing is heard in the presence of a consolidation, a cavity or an advanced disease.

Patients with secondary ILD may also show symptoms and signs of the underlying disease. Patients with CREST syndrome (calcinosis, Raynaud’s phenomenon, esophageal dysfunction, sclerodactyly and telangiectasia) may present with pulmonary hypertension as a primary manifestation. Pulmonary hypertension and chronic cor pulmonale, chronic congestive failure develops in a long-standing disease.[64,65]

Chest Radiography

A diffusely abnormal chest radiograph often is the first leading clue to a diagnosis of ILD, however, a normal chest X-ray does not exclude ILD.[1] The interstitial infiltrates are seen as discrete linear, nodular or

TABLE 93.2: Clinical clues to specific diagnosis of ILD[66]

Clinical clue	*Diagnostic possibilities*
A. History	
• Age 60 years	IPF
Younger (20-40)	CTD
• Gender	LAM exclusively in women
• Acute onset, fever	Infections, AIP, CTD (acute lupus), AEP, COP, HP, drugs
• History of smoking	RB-ILD, DIP, UIP, PLCH, Goodpasteur's syndrome, less in HP
• Specific exposures	Occupational ILD, pneumoconiosis, HP
• Hemoptysis	Alveolar hemorrhage syndromes, LAM
• Arthralgia	IPF, CTD (arthritis with morning stiffness)
• Skin rash, dysphagia, Raynaud's, skin tightness, dryness	CTD
B. Physical examination	
• Typical 'velcro' crepts	IPF, crepts frequently absent in sarcoidosis
• Inspiratory squeaks	COP
• Clubbing	IPF, DIP, IBD
• Skin involvement	Sarcoidosis, CTD, Vasculitis, Tuberous sclerosis
• Arthritis	CTD, sarcoidosis
• Eye changes (uveitis, conjunctivitis)	Sarcoidosis, CTD
• Muscle weakness	Polymyositis, dermatomyositis
• Neuropathy	Sarcoidosis, CTD
• Lymphadenopathy	Sarcoidosis, CTD

Adapted from reference 66

IPF: idiopathic pulmonary fibrosis: CTD: connective tissue diseases: LAM: lymphangioleiomyomatosis: API: acute interstitial pneumonia: AEP: acute eosinophilic pneumonia: COP: cryptogenic organizing pneumonia: HP: hypersensitivity pneumonitis: RB-ILD: respiratory bronchiolitis associated ILD: DIP: desquamative: UIP: usual interstitial pneumonia: PLCH: pulmonary Langherhan's cell histiocytosis: IBD: inflammatory bowel disease

reticulonodular shadows diffusely distributed in both the lungs. The individual nodular shadows are usually of less than 2 mm in diameter. They may also coalesce and form larger nodules. The shadows are generally bibasilar in distribution in early stages. In later stages, diffuse involvement occurs all over the lungs. Upper lobe involvement suggests diseases such as pneumoconiosis, sarcoidosis and hypersensitivity pneumonias. The abnormalities on chest radiograph often provide useful clues and are a good starting point in narrowing the differential diagnoses (Table 93.3).

Presence of diffuse mottling or ground-glass appearances may suggest an active stage of diffuse alveolitis. Miliary distribution throughout the lung fields is characteristically seen in tuberculosis, pneumoconiosis, and sometimes in sarcoidosis. Occasionally, fluffy alveolar shadows may be present due to the coalescence of interstitial shadows or a complicating infection. In advanced disease, when fibrosis is extensive, the lungs get shrunken and reduced in volume. Small, uniform sized, quadrangular cystic spaces, representing patent bronchioles, give the typical appearances of a honeycomb lung.

High Resolution Computed Tomography

High resolution computed tomographic scanning offers a much better view of lung parenchymal involvement.[67] The classical picture of bibasilar reticular and/or nodular infiltrates, honeycombing and absence of lymphadenopathy support the diagnosis of idiopathic pulmonary fibrosis.[68] Pathology is considered uncertain if radiographic findings are atypical, lung involvement is mild or patchy and/or there is presence of hilar or mediastinal lymphadenopathy. The HRCT scan is of great use in classifying IPF.[59,69,70] The HRCT features of subpleural septal thickening, traction bronchiectasis and ground glass attenuation can be considered as definite UIP and lung biopsy avoided.[71,72] Diseases such as sarcoidosis, histiocytosis and lymphangitis have more characteristic patterns.[66] High resolution computed tomography is also of some help in making a quantitative assessment of pulmonary fibrosis.[73] Spiral CT scan gives an even better resolution, especially in a patient with tachypnea who cannot hold his breath.

Pulmonary Function Tests (PFT)

Most ILDs demonstrate a restrictive defect on spirometry and PFT cannot help in differential diagnosis. They are important however for functional assessment and to monitor therapy. Tidal volumes are generally small and both the vital capacity and the total lung capacity are reduced.[74,75] Expiratory flows are normal or even "supranormal". Airway obstruction, characterized by reduced Forced Vital Capacity (FVC) and forced expiratory flows, can occur in patients with hypersensitivity pneumonias, and in smokers. Reduced diffusing capacity (DLCO) and arterial hypoxemia (reduced PaO_2) may not be present in the early stages. Some degree of arterial hypoxemia on exercise is almost always demonstrable.

Measurements of pulmonary compliance can pick up early lung involvement in CT-ILDs.[6,7]

Bronchoalveolar Lavage

Assessment of cellular response in the BAL fluid, although nonconclusive, may help in the differential diagnosis.[76] BAL may be adequate to diagnose specific infections (e.g. tuberculosis, histoplasmosis, coccidioidomycosis, endemic fungal infections) and selected non-infectious diseases (e.g. PLCH[77]or LAM[78]). Increases in BAL lymphocytes suggest sarcoidosis, HP, or other granulomatous processes. When BAL lymphocytes exceed 50%, HP is likely.[76] Presence of eosinophils (>25%) may suggest acute or chronic eosinophilic pneumonia.[79] However, mild increases in lymphocytes or eosinophils have no diagnostic value.[80] Increase in neutrophils can be seen in a wide array of fibrotic disorders.[81] The interstitial lung diseases differ in the pattern of cytokines expressed in BAL and thus the measurement of cytokine levels could be diagnostically useful.[82] Infective microorganisms such as the *Mycobacteria*, fungi or *Pneumocystis jiroveci* can be isolated from BAL fluid. Presence of lymphocytosis in the BAL fluid is shown to predict a better response to corticosteroid therapy. An increase in the alkaline phosphatase/albumin ratio in BAL fluid on a repeat study reflects progression of fibrosis.[83]

Other Investigations

Although nonspecific, hematological investigations provide useful information. A high Erythrocyte Sedimentation Rate (ESR) of more than 50 mm in the first hour occurs in connective tissue disorders, malignancies, infections and systemic vasculitides. Unexplained anemia is seen in diffuse alveolar hemorrhage and connective tissue diseases. Mild-to-moderate leukocytosis is common in both primary and secondary ILDs. Eosinophilia is more characteristically seen in eosinophilic and hypersensitivity pneumonias, vasculitides, sarcoidosis and drug induced lung disease. Occasionally, there is leukopenia and/or thrombocytopenia.

Abnormal liver or renal function tests suggest the involvement of these organs. Elevated calcium may be seen in sarcoidosis and malignancies. Increased enzymes such as creatinine phosphokinase and aldolase are present in polymyositis and dermatomyositis. Increased Serum Angiotensin Converting Enzyme (SACE) in sarcoidois is quite characteristic but may be seen in silicosis, hypersensitivity pneumonias and other diseases.

A number of immunological parameters are described in connective tissue disorders and other ILDs. Hypergammaglobulinemia, positive serum autoantibodies (e.g. the antinuclear factor) and circulating immune complexes may be seen. Anti-basement membrane antibodies in Goodpasture’s syndrome, Antineutrophil Cytoplasmic Antibody (C-ANCA) in Wegener’s granulomatosis, Churg-Strauss syndrome and systemic necrotizing vasculitis, and anti-Jo-1 antibody in polymyositis-dermatomyositis are generally considered characteristic.

Radionuclide scanning using Gallium-67,[84-85] and Position Emission Tomography (PET) scans[86-87] with glucose Fluorodeoxyglucose (FDG) isotope have a place to identify disease-activity and to predict response to therapy. Similarly, the clearance of aerosolized technetium-99m Diethylene Triamine Penta-acetic Acid (DTPA) is markedly increased in patients with inflammatory lung diseases including sarcoidosis.[88]

Lung Biopsy

Diagnosis of IIPs is fairly specific on clinical features and roentgenographic characteristics seen on HRCT scanning. Lung biopsy is required only when the findings are atypical, to exclude an infection, vasculitis or some other undiagnosed cause of ILD is suspected. It may also help to predict the response to treatment and prognosis of a patient.[89] Patients with usual interstitial pneumonia do worse than those with other histological subsets of IIP. Transbronchial Lung Biopsy (TBLB) with the help of fiberoptic bronchoscopy is less rewarding especially in patients with IPF. In sarcoidosis, the positivity rates of TBLB may be as high as 70 to 80%. Many a patient of IPF cannot be subjected to TBLB in view of an inadequate biopsy size and risks involved with fiberoptic bronchoscopy. Transthoracic or open surgical approach provides a better option to obtain lung tissue.[90,91] Surgical lung biopsy achieves three purposes: (1) establishes a precise diagnosis; (2) assesses the extent of inflammation and fibrosis; (3) identifies a histopathological pattern for IIPs.[92,93]

MANAGEMENT

Treatment options for ILD are limited and traditionally are not successful, especially in the case of IPF. Establishing a clear diagnosis of ILD and identifying a potential etiology is critical in determining appropriate therapeutic interventions. The management of ILD should follow an algorithmic approach (Fig. 93.2). In the absence of a satisfactory, definitive treatment of IPF, most objectives (Table 93.4) are achieved with supportive and symptomatic therapy.[63] Several different groups of drugs are employed in its treatment (Table 93.5). Supportive

TABLE 93.3: Some important clues to specific diagnoses in ILD on investigations

Investigation	*Diagnostic possibilities*
A. Chest radiographs	
• Normal	Sarcoidosis, CTD, RB-ILD
• Increased or preserved lung volumes	RB-ILD, CPFE, LAM, AHP
• Upper lobe predominance	Sarcoidosis, HP, Pneumoconiosis, AS
• Lower lobe predominance	IPF, CTD
• Peripheral (Reverse pulmonary edema)	CEP
• Honeycombing	IPF, CTD, chronic HP
• Spontaneous Pneumothorax	LAM, PLCH,
• Pleural effusions	CTD, asbestosis, sarcoidosis
• Fleeting infiltrates	COP, HP
• Miliary pattern	Infections, HP, Sarcoidosis
B. High resolution CT scans	
• Interlobular and intralobular septal thickening, honeycombing, traction bronchiectasis	CTD, IPF, Asbestosis
• Alveolar shadows, ground glassing	COP, AIP, PAP, AEP
• Nodules	Sarcoidosis, Pneumoconiosis, RA
• Cystic ILD	LAM, PLCH, LIP
C. Laboratory investigations	
• Eosinophilia	AEP, CEP
• Iron deficiency anemia	DAH
• Leukopenia/thrombocytopenia	CTD
• Creatinine kinase, Jo-1 antibody	Polymyositis
• ANA, RF	CTD, IPF (low titers)
• Serum precipitins to specific antigens	HP
• ANCA, Anti-GBM antibodies	Vasculitides, Goodpasture's syndrome

1. Provide symptom-relief
2. Slow down disease progression
3. Prevent complications
4. Improve quality of life
5. Prolong survival
6. Prevent treatment-complications
7. End-of-Life care and palliative treatment

TABLE 93.5: List of drugs used in the treatment of ILD

Treatment of Primary ILD

1. Anti-inflammatory drugs
    - Corticosteroids
    - Azathioprine
    - Cyclophosphamide
2. Anti-fibrotic agents
    - Colchicine
    - Pirfenidone
    - Pentoxifylline
    - D-Penicillamine
    - TGF beta antagonist
    - Interferon-gamma
3. Anti-oxidant agents
    - N-Acetyl Cysteine
    - Nitric Oxide Synthase inhibition
4. Receptor antagonists
5. Anti-Apoptosis agents
6. Anti-Angiogenesis agents

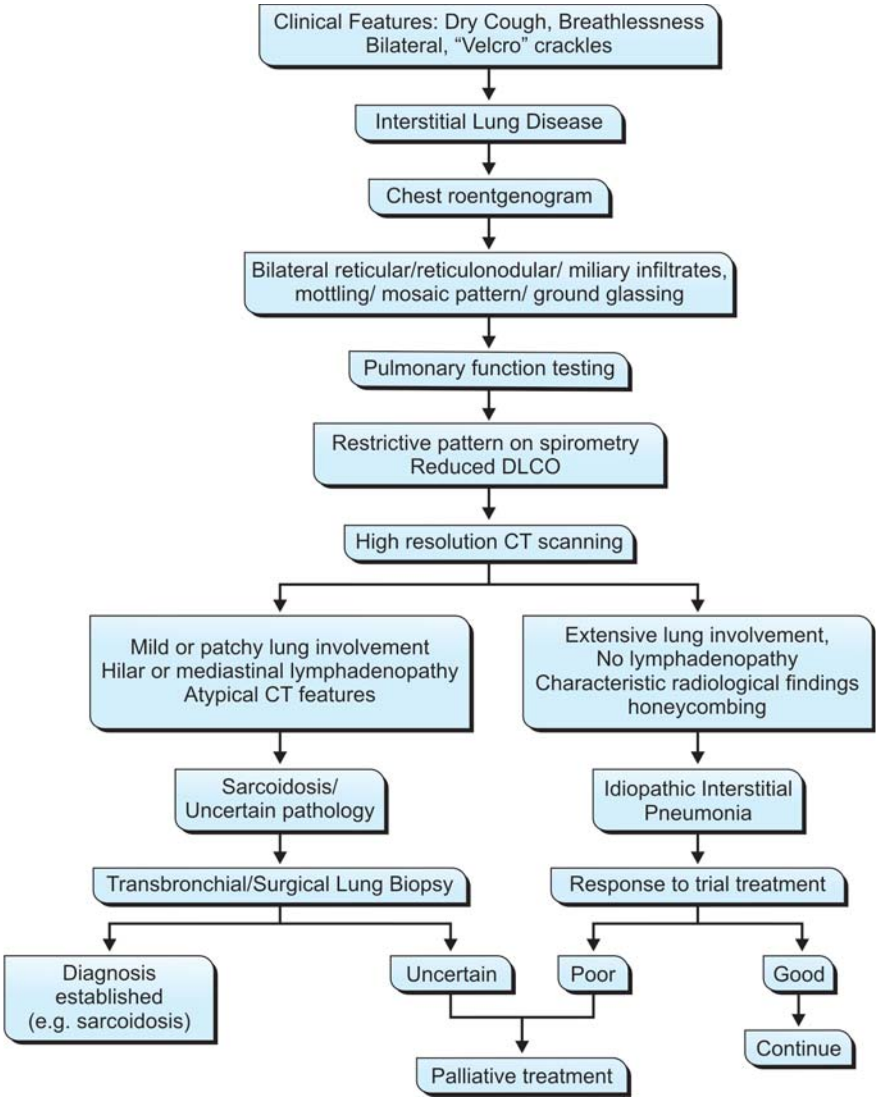
Supportive and symptomatic drugs

1. Oxygen
2. Pulmonary vasodilators
3. Diuretics
4. Antibiotics (if infection)

Rehabilitation

1. Nutrition and dietary supplements
2. Graded, regulated exercises

treatment is provided for respiratory failure, pulmonary hypertension, cor pulmonale and congestive cardiac failure, wherever indicated. Long-term pulmonary vasodilators are not shown to prevent the development of pulmonary hypertension. An acute increase in symptoms and presence of fever with or without mucopurulent expectoration raise the suspicion of a respiratory infection necessitating treatment with antibiotics. To assess the response to therapy and monitor



Clinical Features: Dry Cough, Breathlessness
Bilateral, "Velcro" crackles

its progress a Clinical, Roentgenological and Physiological (CRP) score has been used in the past. It is difficult to frequently repeat invasive investigations such as the bronchoalveolar lavage or lung biopsy. It is generally adequate to rely on clinical picture, simple spirometry and a plain chest roentgenogram. The American Thoracic Society has published therapeutic guidelines for specific subtypes of ILD.[1] Broad approaches are discussed here:

Anti-Inflammatory Therapy

Anti-inflammatory therapy has remained the mainstay of treatment. Minimal to significant improvement is reported with the use of anti-inflammatory agents. But their efficacy remains unproven and the toxicities are substantial. The commonly used criteria to start anti-inflammatory treatment include the presence of severe or worsening clinical symptoms, younger age of the patient and shorter duration of illness.

Despite their widespread use only 10 to 30% of patients with IPF improve on quantitative assessment when treated with corticosteroids.[94] Forty percent respond on the basis of subjective or undefined assessment criteria (because of placebo effects or mood-enhancing effects of corticosteroids). Responses are usually partial and transient. If responses are to occur with corticosteroids, improvement is usually noted within three months. Prednisolone is administered in a dose of 1 to 1.5 mg/kg for a period of about 6 to 12 weeks. Maintenance dose of about 15 to 20 mg daily is continued for one to two years, or more. High-dose intravenous pulse methylprednisolone has no proven advantage over oral corticosteroids.[95]

Treatment with corticosteroids alone is now considered inappropriate. Corticosteroids should be used in conjunction with cytotoxic agents.[96] Other immunosuppressive agents such as azathioprine or cyclophosphamide administered along with prednisolone are shown to do better. In one prospective double blind randomized placebo controlled study with 27 patients, combination of azathioprine and prednisolone had a marginally significant survival advantage.[97] Intravenous cyclophosphamide used as intermittent pulse therapy (1 to 1.3 gm/month) is shown to provide some relief.[98] The role of anti-inflammatory therapy is limited to patients with predominant inflammation. The risks especially of prolonged corticosteroid and other immunosuppressants often outweigh the benefits of therapy. A recent study suggested that combined corticosteroid and cyclophosphamide therapy has no impact on survival in patients with IPF.[99]

Anti-Fibrotic Agents

There is a greater trend to rely on antifibrotic drugs for the treatment. Of the several antifibrotic agents which had been tried, colchicine is considered the safest alternative. It is recommended in a dose of 0.6 to 1.2 mg/day for a period of at least 6 to 12 months. Colchicine inhibits collagen formation and modulates the extracellular milieu and suppresses the release of alveolar macrophage-derived growth factor and fibronectin.[100] Efficacy appears similar to corticosteroids and side effects with colchicine are rarely severe. Initial studies were encouraging with trend towards improved outcome.[101] However subsequent studies have failed to demonstrate any benefit of treatment with colchicine over no treatment at all.[102,103] D-penicillamine and pirfenidone are other drugs which have been tried with variable results.[103,104]

Interferon (IF)-γ inhibits the proliferation of lung fibroblasts in a dose-dependent manner and reduces the synthesis of protein in fibroblasts.[56] This had generated great interest in IF as the magic cure for IPF but subsequent studies dampened the hopes.[105] In a large double-blinded trial with 330 patients with IPF who did not respond to corticosteroid therapy, it was found that IF-γ-1b did not affect progression-free survival, pulmonary function, or the quality of life over 58 weeks. However a trend toward enhanced survival was seen in those who received IF (an absolute reduction in the risk of death of 7% and a relative reduction in the risk of 41%).[106] Increased levels of Interleukin-18 in the induced sputum of patients with IPF have been found to decrease after treatment with IF-γ.[107] A recent meta-analysis showed that IF-γ-1b therapy is associated with reduced mortality.[108] More studies are currently underway to exactly define the safety and efficacy of this form of therapy.[109]

Other Treatments

Antioxidants such as N-acetyl cysteine to reduce oxidative stress are shown to offer some clinical advantage when used along with anti-fibrotic agents. A recent double-blind, randomized, placebo-controlled multicenter study assessed the effectiveness over one year of a high oral dose of acetylcysteine (600 mg three times daily) added to standard therapy with prednisone plus azathioprine.[110] This landmark trial showed that acetylcysteine slowed the deterioration of vital capacity and DLCO at 12 months without significant differences in the type or severity of adverse events.

Drugs targeted to prevent or reduce apoptosis, angiogenesis and coagulant activity may find some use in the future. Presently, no drug from these groups is available for clinical use. It is a better option to resort to symptomatic palliative therapy and withdraw immunosuppressive drugs in case there is no response in the initial three to six months of use and for end-stage disease.

Lung Transplantation

Lung transplantation is the only hope for the advanced, end-stage disease.[111] Single lung transplantation is recommended in most patients. Five years survival is reported in up to 40 to 60% of patients. The common posttransplant complications include the risk of resection, multiple opportunistic infections in an immunosuppressed host and organizing pneumonias. The lack of availability of organ for transplantation and very high costs involved in the procedure are the limited factors. Living-Donor Lobar Lung Transplantation (LDLLT) is a new and evolving option for patients with end-stage lung disease.[112]

Other Supportive Measures

The primary goal in managing a patient with IPF is to restore them to the highest possible functional state. Patients should be encouraged to enroll in a pulmonary physical rehabilitation program. Daily walks or use of a stationary bicycle are useful. Those with hypoxemia at rest or during exercise should be managed by supplemental oxygen. Higher flow rates than those needed in COPD may be frequently required. Dry cough may be controlled with anti-tussives. Low dose opioids are effective and safe in the palliative management of dyspnea in terminally ill IPF patients.[113] Pulmonary hypertension, cor pulmonale and right heart failure, which complicate late stages of IPF, should be appropriately managed. In randomized controlled, open-label trial a phosphodiesterase type 5-inhibitor sildenafil causes preferential pulmonary vasodilatation and improves gas exchange in patients with severe lung fibrosis and secondary pulmonary hypertension.[114]

ACUTE EXACERBATION OF ILD

Acute Exacerbation of Idiopathic Pulmonary Fibrosis (AE-IPF) is a clinical entity defined by the rapid deterioration of IPF during the course of the disease that is not due to infections, pulmonary embolism or heart failure. The condition needs to be differentiated from acute interstitial pneumonia (or Hamman-Rich syndrome), which occurs in patients with no underlying lung disease. The exact etiology and pathogenesis remain unknown, but the condition is characterized by diffuse alveolar damage (on a background of IPF) that probably occurs as a result of a massive lung injury due to some unknown etiologic agent. High-resolution computed tomography can help in prognostication and management of this condition. Once infections and other causes of worsening have been excluded, treatment involves enhanced immunosuppression with pulse doses of methylprednisolone and cytotoxic agents. A systematic review shows that the outcome, however, is poor, with one-month and three-month mortality around 60 and 67%, respectively. Few studies have shown beneficial effects of cyclosporine, pirfenidone, and anticoagulants in the management and prevention of AE-IPF.[115]

PROGNOSIS

Prognosis of ILDs, secondary to systemic diseases or other causes is determined by the natural course of the underlying disease. Prognosis of primary IIPs is variable. While NSIP, DIP and RBILD respond better, the IPF is progressive and fatal. The survival has not significantly improved in the last nearly 50 years or so from that reported in the 1960s. The median survival of IPF is about four years. Acute interstitial pneumonia and acute exacerbation of IPF are rapidly fatal, sometimes in a course of a few weeks or months.[116]

It is unclear how many ILD patients actually die of their lung disease.[15,117] Given the advanced age of many with ILD, patients are at risk for other age-related diseases and need close follow-up. Survival for ILD is worse if at time of diagnosis there is advanced age (>50), male gender, moderate/severe dyspnea on exertion, history of tobacco use, moderate loss of lung function (TLC <45%, DLCO <40%), neutrophilia/eosinophilia on bronchoalveolar lavage, honeycombing on HRCT, lack of a response to corticosteroids, or moderate/severe fibrosis and fibroblastic foci on histology.[118-119]

Pathology of Interstitial Lung Disease

Amanjit Bal, Kusum Joshi

Interstitial Lung Disease (ILD) is a heterogeneous group and refers to a diverse range of acute, subacute and chronic diseases that cause inflammation and fibrosis of the alveoli, distal airways and septal interstitium of the lungs. The "interstitium" is a connective tissue framework, abundant around the airways and arteries in the center of the lobules and around the veins at the periphery. At the alveolar level, it includes the space between the epithelial and endothelial basement membranes. It consists of collagen and elastin fibers (fibroblasts and myofibroblasts), histiocytes, lymphocytes, dendritic cells, Langerhans cells and mast cells. Though ILD dominantly involves the interstitium, these disorders may affect the airspaces, peripheral airways and blood vessels along with their respective epithelial and endothelial linings. Hence, an alternative term of Diffuse Parenchymal Lung Disease (DPLD) has been used to define the same group of disorders (Table 94.1).

IDIOPATHIC INTERSTITIAL PNEUMONIA

The Idiopathic Interstitial Pneumonias (IIPs) are a group of diffuse parenchymal diseases of unknown etiology. The American Thoracic Society/European Respiratory Society (ATS/ERS) sponsored committee comprising of the clinicians, radiologists and pathologists developed a consensus classification system for IIPs.[1] This classification was based on the seven histopathologic patterns seen on surgical lung biopsies.

Pathogenesis of Idiopathic Interstitial Pneumonias

Despite intensive research, the etiology and pathogenesis of idiopathic interstitial pneumonias remain poorly understood. Increased number of inflammatory cells in Bronchoalveolar Lavage (BAL) in patients with IIPs, led to the prevailing hypothesis that disease process begins as an "alveolitis" and progresses to interstitial fibrosis. It is speculated that chronic inflammatory process injures the lung and modulates fibrogenesis, leading to the end-stage fibrotic scar. Tansforming Growth Factor-Beta

TABLE 94.1: Classification of Interstitial (Diffuse Parenchymal) Lung Disease

I. **Idiopathic Interstitial Pneumonias**
  - Usual Interstitial Pneumonia/Idiopathic Pulmonary Fibrosis (UIP/IPF)
  - Nonspecific Interstitial Pneumonia (NSIP)
  - Desquamative Interstitial Pneumonia (DIP)
  - Respiratory Bronchiolitis associated Interstitial Lung Disease (RB-ILD)
  - Acute Interstitial Pneumonia (AIP)
  - Lymphoid Interstitial Pneumonia (LIP)
  - Cryptogenic Organizing Pneumonia (COP)

II. **Multisystem Diseases**
  - Sarcoidosis
  - Connective tissue disorders
  - Drug Reactions

III. **Environmental and Occupational Diseases**
  - Pneumoconiosis
  - Hypersensitivity pneumonitis/Extrinsic allergic alveolitis

IV. **Rare Lung Diseases**
  - Lymphangioleiomyomatosis
  - Pulmonary alveolar proteinosis
  - Pulmonary Langerhans cell histiocytosis
  - Pulmonary eosinophilia
  - Idiopathic pulmonary hemosiderosis

(TGF-α) activation which is responsible for maintaining the mesenchymal cells and regulating Extracellular Matrix (ECM) synthesis and degradation is a proposed key element in promoting the progression of pulmonary fibrosis.[2] Though at present the inflammatory cells are the principle source for fibrogenic mediators, but there is evidence that supports the essential role of activation of alveolar epithelial cells after injury. Alveolar epithelial cells are being considered as the main source of Platelet-Derived Growth Factor (PDGF), TGF-β1, Tumor Necrosis Factor-Alpha (TNF-α), Endothelial (ET)-1 and Connective Tissue Growth Factor (CTGF); the mediators implicated in the pathogenesis of pulmonary fibrosis.

Utility of Bronchoalveolar Lavage (BAL) and Lung Biopsy

Bronchoalveolar lavage is useful for detecting infections as a cause of diffuse lung infiltrates. The method consists of instilling saline via a bronchoscope wedged in a segmental bronchus, which gets exposed to a large area of the parenchyma and then aspirating and collecting the same. Opportunistic infections in the immunosuppressed can be easily diagnosed. An excess of lymphocytes can be indicative of sarcoidosis; whereas, an increase in neutrophils and eosinophils is typically found in idiopathic pulmonary fibrosis. Rarely, langerhans cells can be identified in a case of langerhans' cell histiocytosis. Hemosiderin laden macrophages indicate old hemorrhage in pulmonary hemosiderosis, vasculitis or other causes.

Lung biopsy is often required to clinch the diagnosis. Although, lung biopsy is said to be the gold standard, it is limited by the fact that only a small tissue is being sampled in a disease which is heterogeneous from area to area. Transbronchial lung biopsy is usually inadequate for the diagnosis as it samples only centrilobular areas; however, it may be of value to diagnose organizing pneumonia, and RB-ILD and to exclude granulomatous lesions, neoplasms as well as infectious etiologies. Thus surgical lung biopsy is almost always required to determine the histological pattern in idiopathic interstitial pneumonias. It is important to avoid areas of end stage disease and biopsies from multiple sites provide diagnostic tissue and reduce sampling errors.

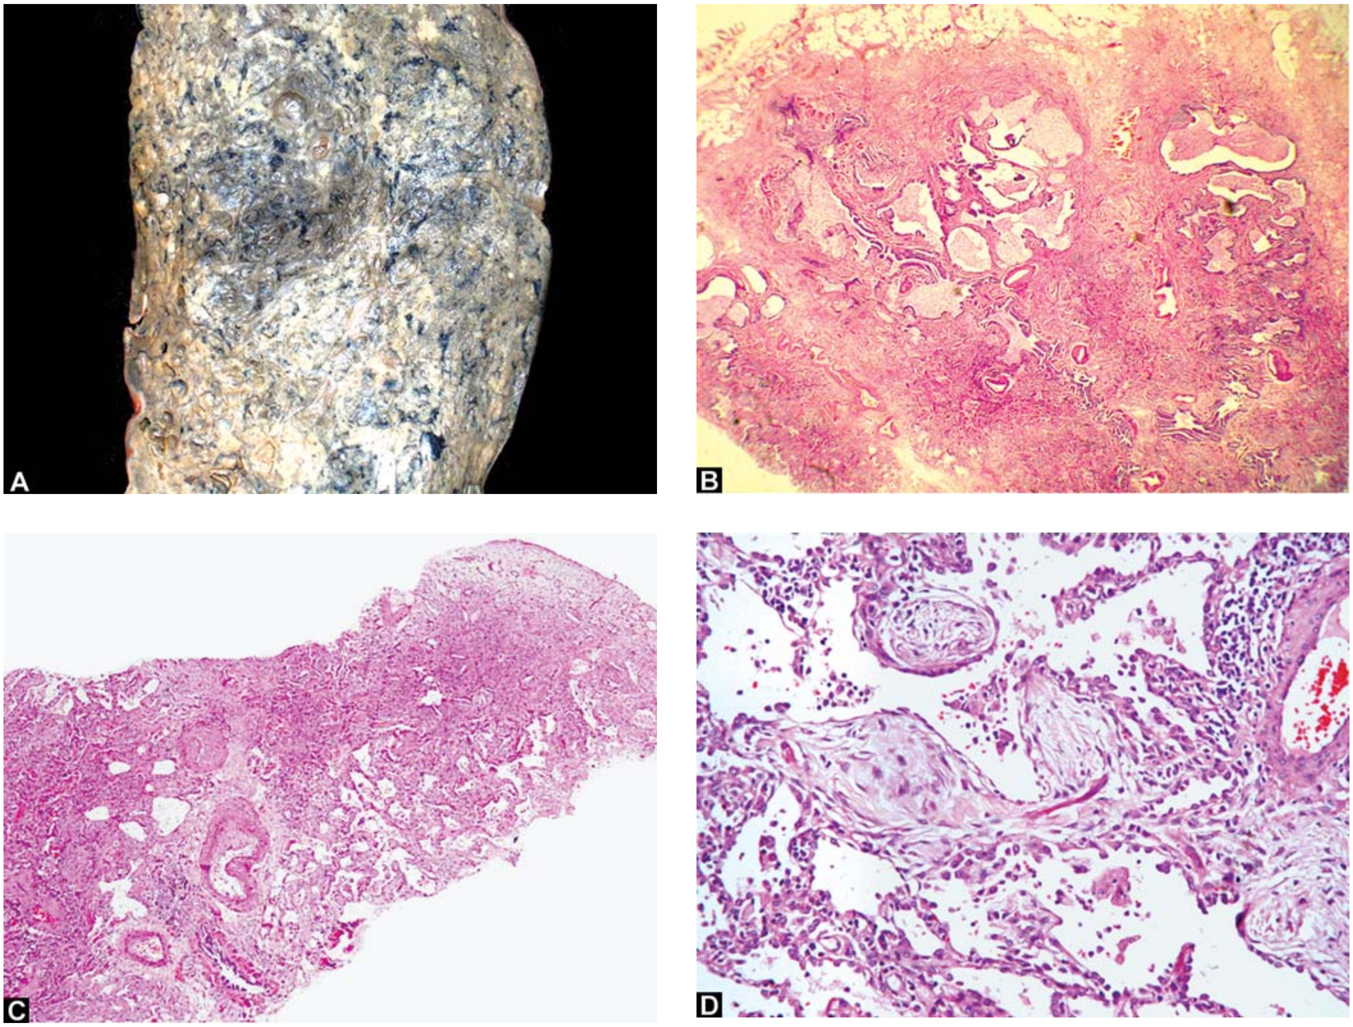
Usual Interstitial Pneumonia (UIP)

Usual interstitial pneumonia is the most common of idiopathic interstitial pneumonias. Idiopathic Pulmonary Fibrosis (IPF) and UIP are interchangeable terms; IPF being a chronic fibrosing interstitial pneumonia of unknown cause with a surgical lung biopsy showing a histologic pattern of UIP.[3] Patients with UIP usually present in the sixth or seventh decade of life with slowly progressive dyspnea and cough. Pulmonary function studies show restrictive abnormalities, and/or impaired gas exchange, decreased PaO_2 with rest or exercise, or decreased diffusing capacity of the lung for carbon monoxide. High Resolution Computed Tomography (HRCT) shows a characteristic combination of peripheral (subpleural), irregular, linear "reticular" opacities involving predominantly the lower lung zones with associated architectural distortion in the form of traction bronchiectasis and honeycomb change.

Histopathological features: UIP is a specific morphological entity defined by a combination of (i) fibrosis distributed in a heterogeneous fashion, (ii) fibroblastic foci, and (iii) honeycomb change and scars.[4] On examination at low magnification, UIP is characterized by "spatial heterogeneity" and nonuniform distribution of the inflammatory and fibrosing process (Fig. 94.1A). These morphological changes are sharply demarcated from the adjacent normal areas. The fibrosis is more marked at the periphery and paraseptal region in the lower lobes. The other cardinal feature of UIP is the presence of active fibroblastic foci which comprises of plump spindle cells with little intervening collagen (Fig. 94.1B). The other areas of fibrosis show poorly cellular foci with deeply eosinophilic hyalinized collagen. This variation in age of fibrosis is termed as "temporal heterogeneity." The inflammatory component in UIP is usually mild to moderate and is composed of lymphocytes and plasma cells with occasional aggregate formation. In advanced stages, fibrosis leads to distortion of the lung parenchyma and cystic dilatation of air spaces resulting in end stage lung or honeycomb change (Fig. 94.1C). The end stage lung shows bronchiolar metaplasia of alveoli, prominence of type II pneumocytes and smooth muscle hyperplasia (Fig. 94.1D). These end stage changes when florid has been termed as "muscular cirrhosis" of the lungs. Vascular changes in the scarred areas show intimal proliferation and medial hypertrophy resulting in endarteritis obliterans.

Nonspecific Interstitial Pneumonia (NSIP)

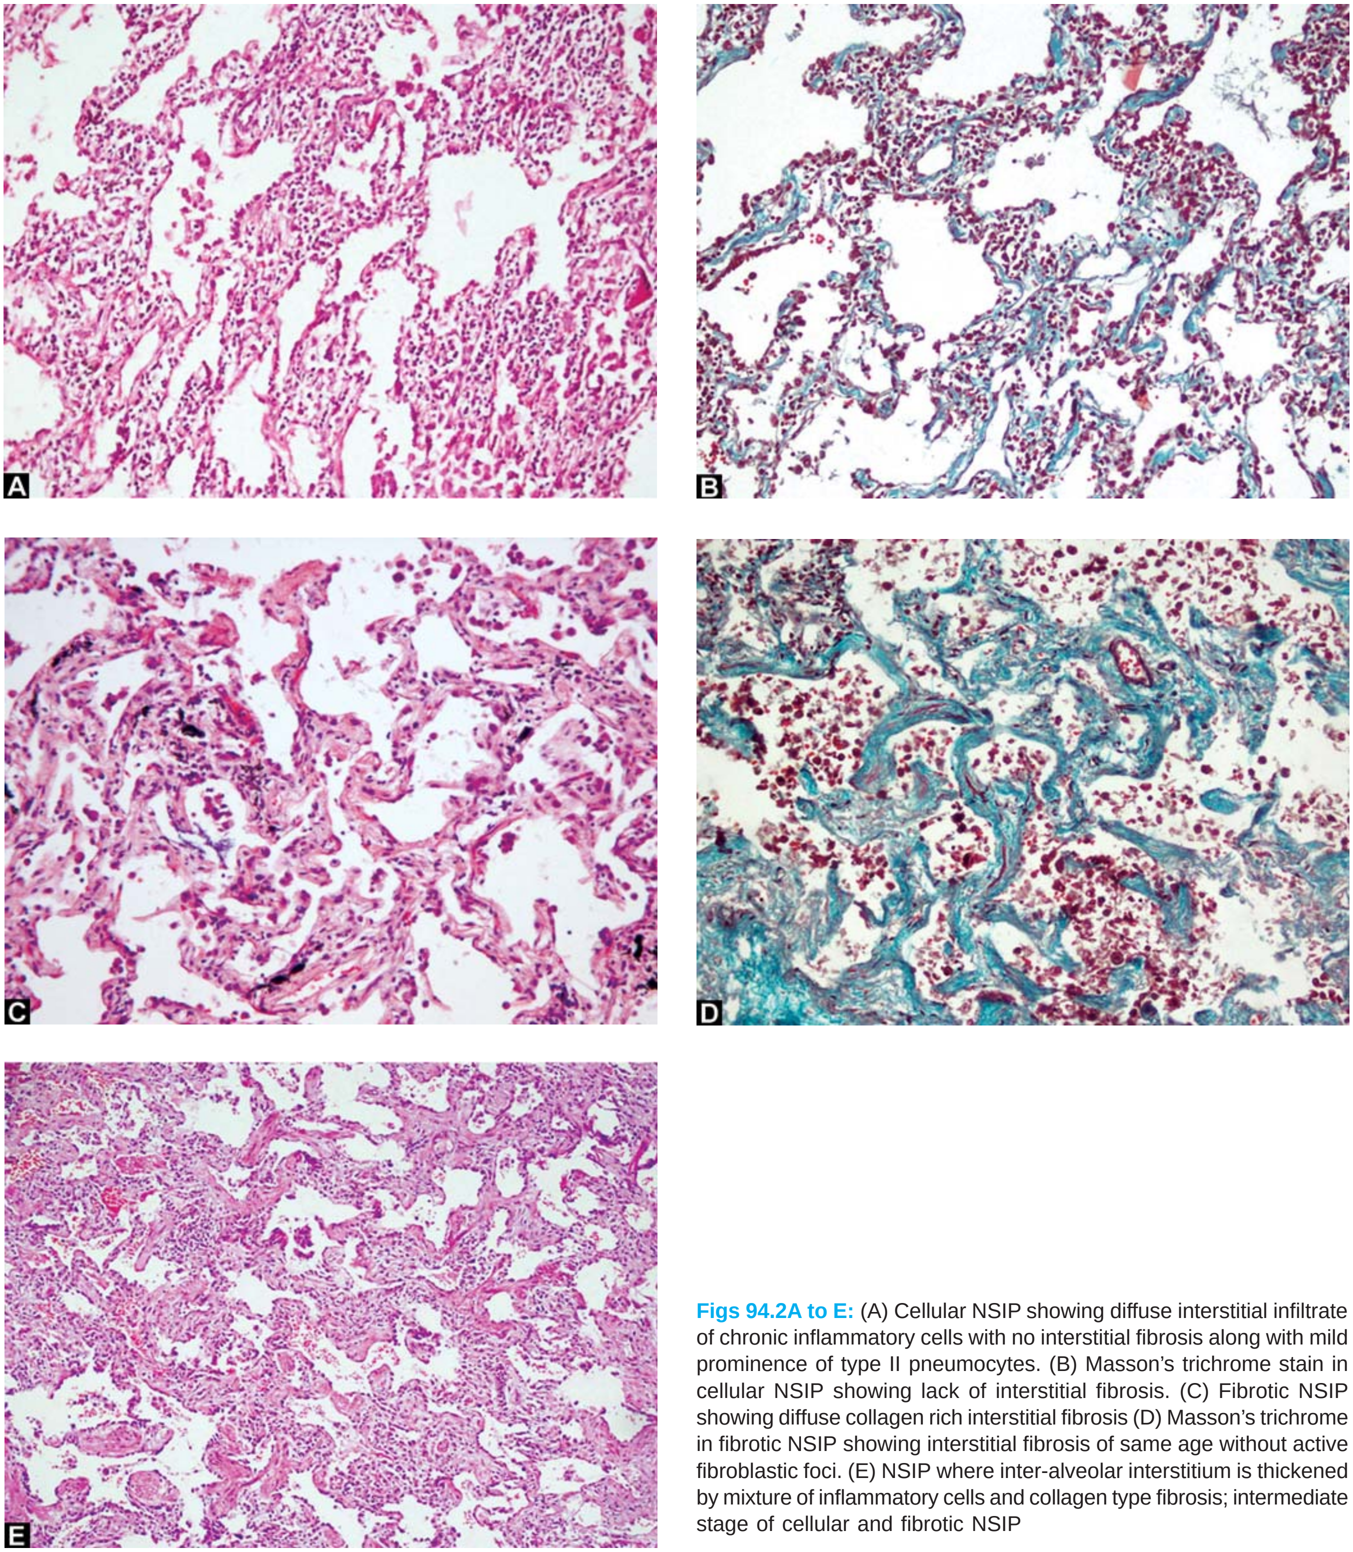
Nonspecific interstitial pneumonia is regarded as provisional in ATS/ERS consensus classification and is used for cases that do not fulfill the diagnostic criteria of UIP, DIP and RB-ILD. Nonspecific interstitial pneumonia is currently the second most common (after UIP) histopathological pattern of the idiopathic interstitial



Figs 94.1A to D: (A) Gross photograph of cut surface of the lung in usual interstitial pneumonia showing extensive peripheral honeycombing. (B) Photomicrograph of honeycomb change in UIP characterized by enlarged airspaces lined by bronchiolar type of epithelium, surrounded by dense fibrosis and lumen filled with mucin and inflammatory cells. (C) Patchy heterogeneous inflammation and fibrosis with subpleural localization, and alternating with normal lung parenchyma in a case of UIP. (D) Fibroblastic foci composed of plump spindle shaped fibroblasts in the interstitium and lifting the alveolar lining epithelial cells in UIP

pneumonias and is characterized by a temporally and spatially uniform pattern that suggests that the lesions are of the same age.

Histopathological features: Nonspecific interstitial pneumonia is characterized by "temporal homogeneity". Nonspecific interstitial pneumonia has three major subgroups based on the amount of inflammation and/or fibrosis in the lung biopsies: **Group I (Cellular NSIP):** Primarily with interstitial inflammation, **Group II**: With both inflammation and fibrosis, and **Group III (Fibrotic NSIP):** Primarily with fibrosis.[4] The cellular end of the spectrum has mild-to-moderate interstitial inflammation comprising of lymphocytes and plasma cells with minimal or no fibrosis (Fig. 94.2A and B). The fibrotic end of spectrum shows interstitial fibrosis composed of mature collagen and only a few fibroblasts (Fig. 94.2C and D). Intermediate stage of cellular and fibrotic NSIP shows mixture of inflammatory cells and collagen type fibrosis (Fig. 94.2E). The lung architecture may appear to be lost on examination of routine hematoxylin and eosin-stained sections, but is relatively preserved with elastic stains. NSIP lacks alveolar remodeling with honeycomb cyst formation and active fibroblastic foci distinguishing it from UIP.[5]

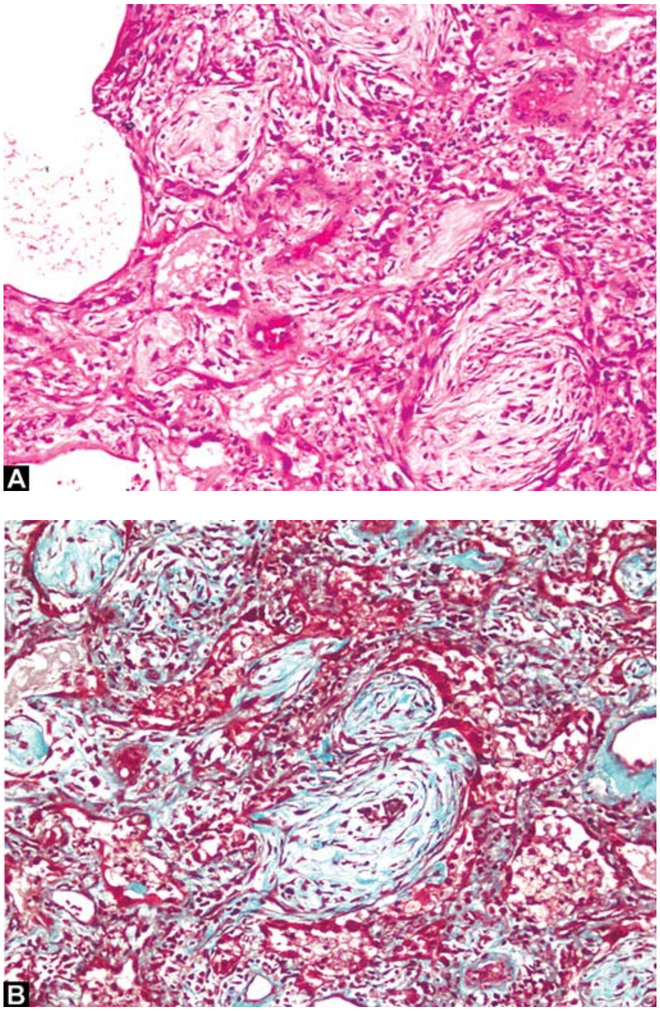


Figs 94.2A to E: (A) Cellular NSIP showing diffuse interstitial infiltrate of chronic inflammatory cells with no interstitial fibrosis along with mild prominence of type II pneumocytes. (B) Masson's trichrome stain in cellular NSIP showing lack of interstitial fibrosis. (C) Fibrotic NSIP showing diffuse collagen rich interstitial fibrosis (D) Masson's trichrome in fibrotic NSIP showing interstitial fibrosis of same age without active fibroblastic foci. (E) NSIP where inter-alveolar interstitium is thickened by mixture of inflammatory cells and collagen type fibrosis; intermediate stage of cellular and fibrotic NSIP

Cryptogenic Organizing Pneumonia (COP)

Organizing pneumonia is a histologic pattern of repair in response to injury. It is characterized by air space filling fibrosing process that involves distal bronchioles, alveolar ducts and peribronchiolar alveolar spaces. Different terminologies have been used for this lesion which includes; Bronchiolitis Obliterans-Organizing Pneumonia (BOOP) in cases where luminal fibrosis is seen in the bronchioles as well; Cryptogenic Organizing Pneumonia (COP), a preferred term for idiopathic disease. ATS/ERS consensus classification has proposed the term Organizing Pneumonia (OP) for the histologic pattern on biopsy. Bronchiolitis obliterans is not seen in every case, thus the terminology of OP reduces the emphasis of this finding, while COP is the clinical term for idiopathic form of this disease. Organizing pattern of ILD is seen secondary to various underlying etiologies like infections; bacterial, viral and fungal, collagen vascular diseases and drugs.

Histopathological features: Organizing pneumonia is characterized by patchy areas of loose fibroblastic intraluminal plugs involving alveolar ducts and alveolar spaces.[6] This process is centered on bronchioles and obliterative bronchiolitis may be seen in many cases. These intraluminal fibroblastic plugs called "Masson's bodies" are rich in mucopolysaccharides and assume the oval, elongated or serpiginous shapes of airspaces in which they are formed (Figs 94.3A and B). The adjoining inter-alveolar interstitium shows varying degrees of inflammatory infiltrate. In addition there is accumulation of foamy, lipid containing macrophages in the airspaces that represent postobstructive or endogenous lipoid pneumonia due to bronchiolar obstruction.

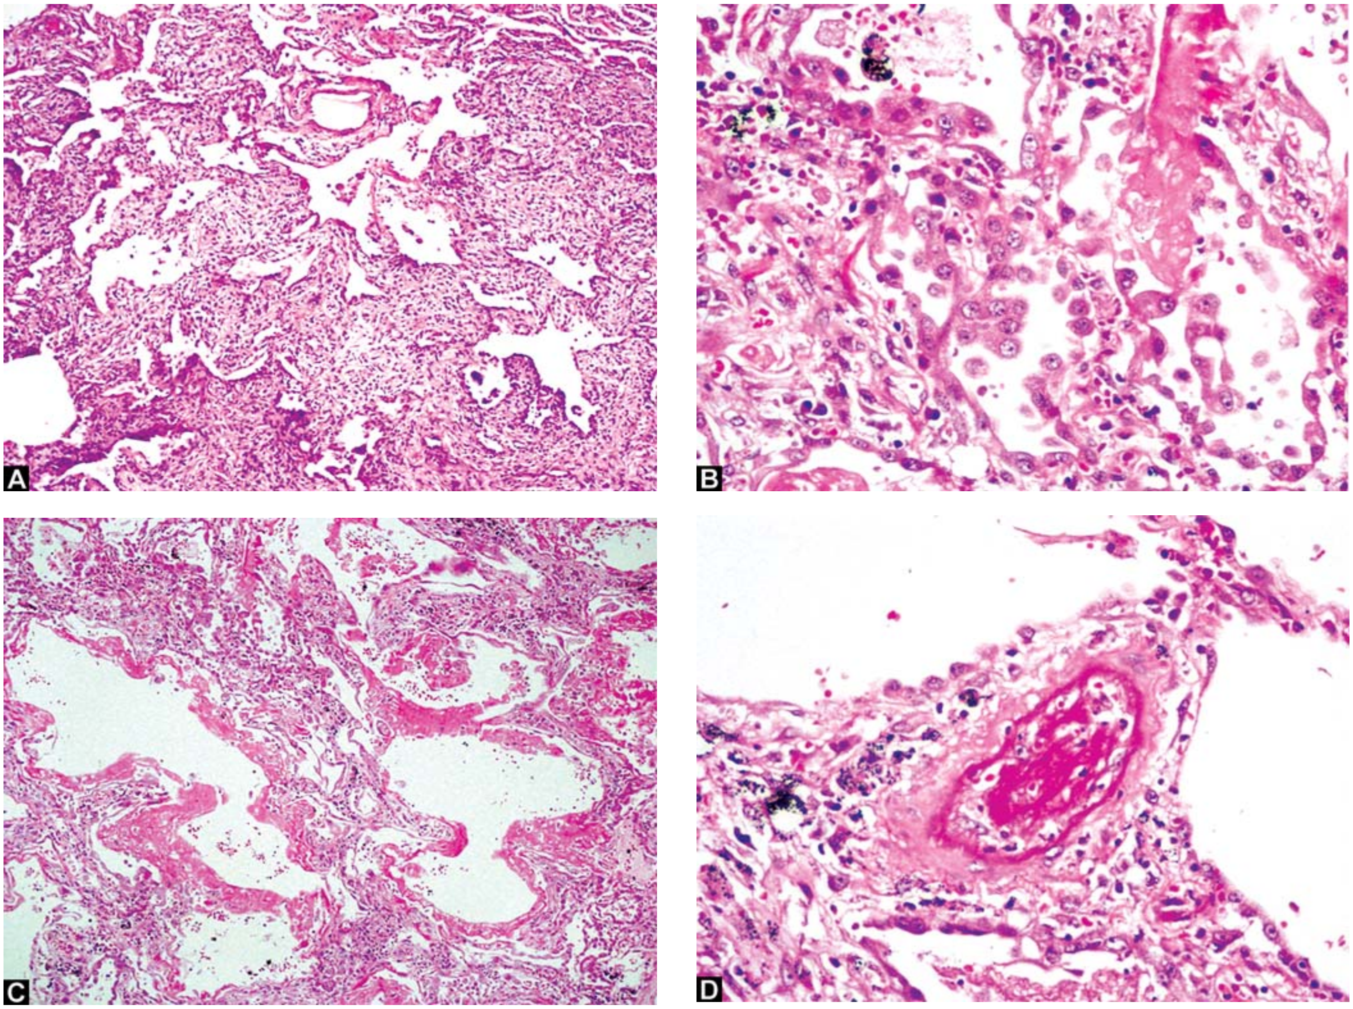


Figs 94.3A and B: (A) Loose plugs of fibroblastic tissue, "Masson's bodies" filling the alveolar spaces in organizing pneumonia. (B) Masson's trichrome highlighting the intraluminal fibroblastic plugs in organizing pneumonia

Acute Interstitial Pneumonia (AIP)

Acute interstitial pneumonia is a Diffuse Alveolar Damage (DAD) occurring in an idiopathic setting. It is a very aggressive form of ILD that may occur as an acute phase of acceleration of UIP and is as also termed as Hamman-Rich disease. AIP is the least common and rapidly progressive histologically distinct form of interstitial pneumonia analogous to Acute Respiratory Distress Syndrome (ARDS) caused by sepsis and shock.[7] Patients with AIP present with rapidly evolving shortness of breath and non-productive cough of one to three weeks duration preceded by a flu-like illness. Most patients are severely hypoxemic at the time of diagnosis and require hospitalization and mechanical ventilation. High resolution computed tomography shows ground glass attenuation and consolidation in a bilateral and symmetrical distribution.

Histopathological Features: Biopsy specimens from patients with AIP demonstrate DAD, usually in the late or organizing stage. The lung biopsy typically shows diffuse involvement, although there may be variation in the severity of the changes among different histologic fields. Alveolar septa are thickened and distorted by proliferating spindle cells (fibroblasts and myofibroblasts) within a pale-staining basophilic matrix (Fig. 94.4A). The uniformity of the findings contrasts sharply with the heterogeneous distribution of varying abnormalities in UIP. Fibroblast proliferation is



Figs 94.4A to D:(A) Organizing phase of acute interstitial pneumonia showing marked interstitial thickening by prominent fibroblast proliferation and scanty inflammatory infiltrate. (B) Proliferation and prominence of type 2 pneumocytes in acute interstitial pneumonia. The lining alveolar epithelial cells are hobnail shaped and have prominent nucleoli. (C) Exudative phase of acute interstitial pneumonia showing hyaline membranes lining alveolar ducts and alveolar spaces. The alveolar septa are thickened by interstitial edema. (D) Fibrin thrombi in small vessels in acute interstitial pneumonia

accompanied by marked hyperplasia of type II pneumocytes which may show cytological atypia characterized by nuclear enlargement and prominent nucleoli (Fig. 94.4B). Remnants of hyaline membranes may be present in some cases, but are often inconspicuous. Hyaline membranes are a histologic hallmark of DAD in early exudative phase and their presence is helpful in the distinction from the UIP, NSIP or organizing pneumonia patterns (Fig. 94.4C). Thrombi in small to medium-sized pulmonary arterioles and squamous metaplasia of bronchiolar epithelium which are features of acute lung injury can provide an important clue to the diagnosis (Fig. 94.4D).

No histological features can reliably distinguish DAD in the setting of AIP from DAD of other known causes. Therefore, before making a diagnosis of AIP all potential causes of DAD should be excluded. The presence of granulomas, viral inclusions, foci of necrosis or neutrophilic abscesses suggest infection.

Respiratory Bronchiolitis-associated Interstitial Lung Disease (RB-ILD)

Respiratory bronchiolitis-associated interstitial lung disease is the clinical manifestation of interstitial lung disease associated with the pathologic lesion of respiratory bronchiolitis. Respiratory bronchiolitis affects younger patients, with a mean age at diagnosis in the fourth or fifth decade of life. Nearly all patients have strong histories of cigarette smoking, thus RB-ILD is being considered as a smoking-related interstitial lung disease. It is rarely symptomatic and is usually associated with no more than minor small airway dysfunction. In rare cases the condition presents as a form of interstitial lung disease with significant pulmonary symptoms, abnormal pulmonary function and imaging abnormalities. It is then described as Respiratory Bronchiolitis-associated Interstitial Lung Disease (RB-ILD).[8] HRCT shows patchy ground glass opacities and centrilobular nodules often with a lower lung zone distribution, without fibrotic scars and honeycomb change.

Histopathological Features: In respiratory bronchiolitis the changes are patchy at low magnification and have a bronchiolocentric distribution. Respiratory bronchioles, alveolar ducts, and peribronchiolar alveolar spaces contain clusters of pigmented (smoker's) macrophages (Fig. 94.5). The macrophages have abundant cytoplasm containing finely granular dusty brown pigment that stains faintly with perls' stain. Mild peribronchiolar fibrosis is also seen that radiates to and expands contiguous alveolar septa, which are lined by hyperplastic Type II pneumocytes. It is also frequently associated with the presence of centrilobular emphysema and not uncommonly encountered as an incidental finding in the context of other forms of lung disease.

Desquamative Interstitial Pneumonia (DIP)

Desquamative interstitial pneumonia is a rare form of ILD that affects smokers and is characterized by the desquamation of alveolar macrophages with minimal fibrosis. Previously the intraalveolar cells were thought to represent alveolar epithelial cells that had desquamated from alveolar septa. This condition is considered by many to represent the end of a spectrum of RB-ILD in view of its similar pathology and almost invariable association with cigarette smoke.[9]

Histopathological Features: The DIP pattern is characterized by diffuse involvement of the lung by numerous macrophage accumulations within most of the distal airspaces (Fig. 94.6). The alveolar macrophages form loose clusters and have round nuclei with abundant eosinophilic cytoplasm containing golden brown pigment that stains weakly with perl's stain. The alveolar septa are thickened by a sparse inflammatory infiltrate that often includes plasma cells and occasional eosinophils, and they are lined by plump type II pneumocytes. The main feature that distinguishes DIP from RB-ILD is that the former affects the lung in a uniform diffuse manner and lacks the bronchiolocentric distribution seen in RB-ILD.

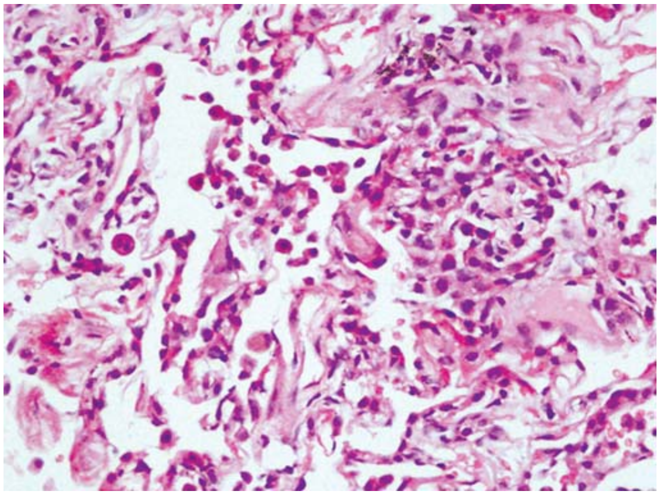


Fig. 94.5: Respiratory bronchiolitis associated interstitial lung disease showing collection of smoker's macrophages in respiratory bronchiole and adjoining alveolar spaces

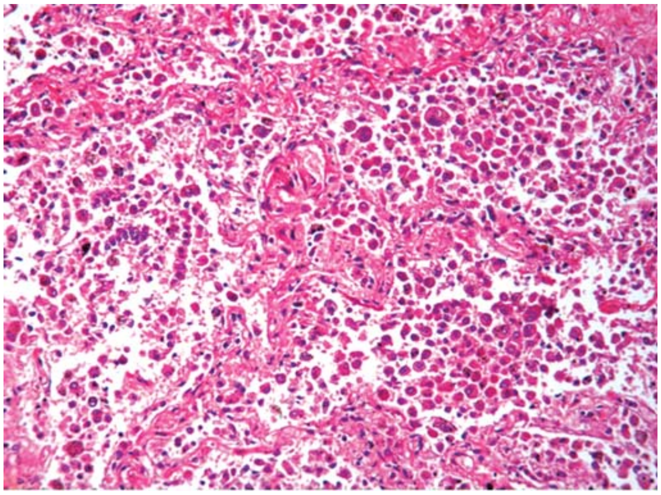

Fig. 94.6: Desquamative interstitial pneumonia showing diffuse distribution of macrophages in the alveolar spaces. Macrophages have abundant eosinophilic cytoplasm with granular brown pigment

DIP-like Reactions: Areas resembling RB-ILD and DIP are commonly seen as incidental findings in cigarette smokers with other lung diseases. No histological changes can reliably separate patients with RB-ILD/DIP from those with other lung diseases in whom RB and "DIP-like reactions" represent incidental findings. Thus RB-ILD/DIP should be diagnosed only when other forms of interstitial lung diseases have been excluded by careful examination of the surgical lung biopsy, clinical features and radiological findings.

Lymphoid Interstitial Pneumonia (LIP)

Lymphoid interstitial pneumonia is characterized by the expansion of the interstitium by sheets of lymphoid cells that are histologically benign and immunophenotypically polyclonal. It may be idiopathic in nature or occurs in association with connective tissue diseases, autoimmune diseases or Human Immunodeficiency Virus (HIV) infection. In a small number of cases LIP undergoes transformation to lymphoma. Lymphoid interstitial pneumonia is perhaps best regarded as a histologic variant of diffuse pulmonary lymphoid hyperplasia with predominant interstitial changes.

Histopathological features: Lymphoid interstitial pneumonia is defined as a dense and diffuse interstitial lymphoid infiltrate, comprising of lymphocytes, plasma cells and histiocytes (Fig. 94.7). The alveolar septa should be extensively infiltrated and lymphoid follicles including follicles with germinal centers are often present. Some architectural derangement (including honeycombing) and non-necrotizing granulomas may be seen. The pertinent negative findings are lack of tracking along lymphatic routes (bronchovascular bundles, pleura and interlobular septa) which are characteristic of lymphomas, inconspicuous or absent organizing pneumonia, lack of Dutcher bodies, lack of monoclonality on immunohistochemistry for light chains, lack of extensive pleural involvement or lymph node involvement and lack of necrotizing granuloma.[1,10]

The differential diagnosis for LIP includes diffuse lymphoid hyperplasia (hyperplasia of bronchial mucosa-associated lymphoid tissue), nodular lymphoid hyperplasia, lymphoma [of Mucosa-Associated Lymphoid Tissue (MALT) or small lymphocytic types], and the patterns of OP, NSIP, hypersensitivity pneumonitis, and UIP.[1] The hypersensitivity pneumonitis tends to have lesser inflammation, a peribronchiolar distribution, poorly formed granulomas and intraluminal organizing fibrosis. There are no precise criteria to distinguish LIP and cellular NSIP, but it has been observed that the extent of interstitial lymphocytic and/or plasma cell infiltrate is generally less severe in NSIP. The Bronchus-Associated Lymphoid Tissue (BALT) differs from LIP in that it lacks extensive alveolar septal infiltration. Malignant lymphomas show a monomorphous population of lymphoid cells with the destruction of alveolar architecture, pleural infiltration and tracking along lymphatic routes.

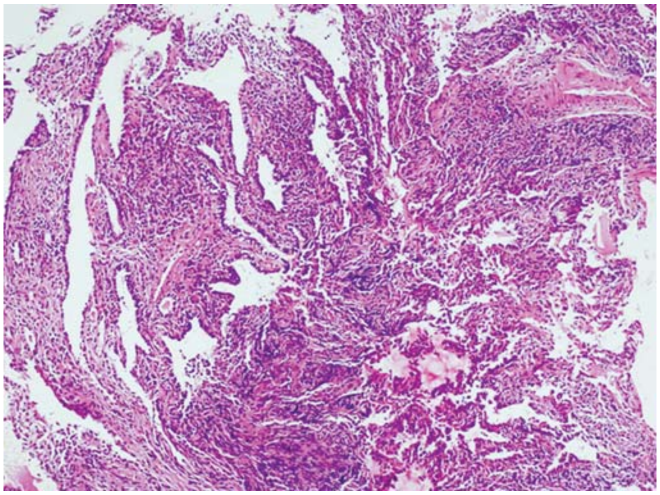

Fig. 94.7: Lymphocytic interstitial pneumonia showing diffuse dense lymphomononuclear cell infiltrate in the interstitium

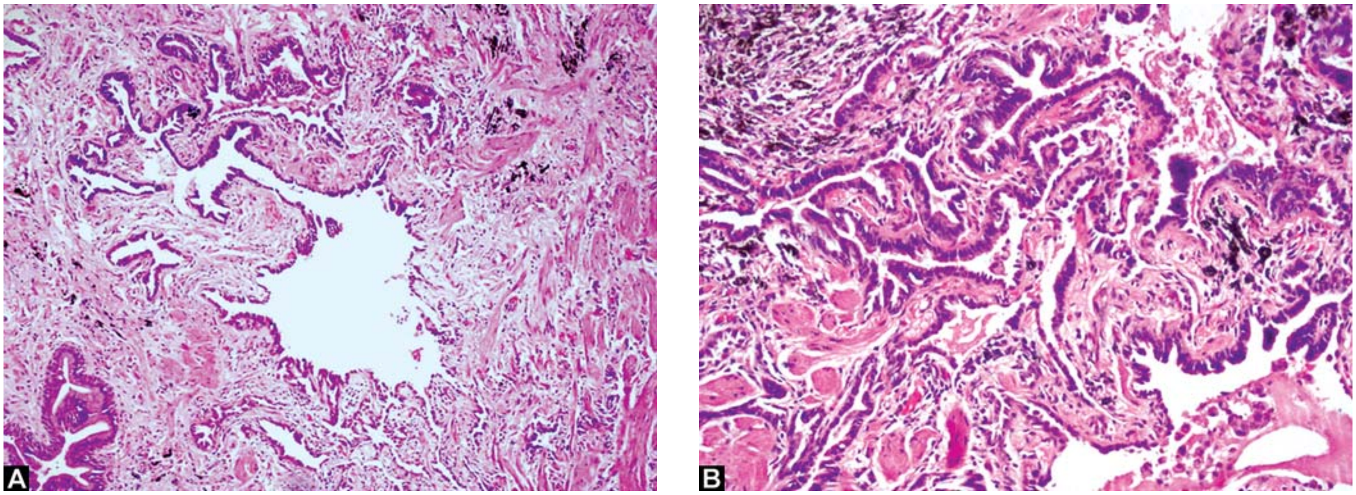
IDIOPATHIC BRONCHIOLOCENTRIC INTERSTITIAL PNEUMONIA (BrIP)/AIRWAY CENTERED INTERSTITIAL FIBROSIS

Idiopathic bronchiolocentric interstitial pneumonia is a new entity described after 2002 ATS/ERS consensus classification. It is a bronchiolocentric process associated with centrilobular peribronchiolar fibrosis and distal lymphocytic alveolitis.[11] Patients present with symptoms, such as progressive dyspnea and dry cough. Studies have reported female predominance and history of inhalational exposure to smoke, birds, cotton and agrochemicals. Chest radiographs and HRCT shows bilateral dominant lower lobe reticular and reticulo-nodular infiltrates. Like other interstitial pneumonias, BrIP is associated with functional restrictive lung disease.

Histopathological Features

The most striking finding is centrilobular and bronchiolocentric nature of inflammatory infiltrate.[12,13] The inflammation extends into the peribronchiolar alveolar septa and distal interstitium of the acinus. There is relative sparing of the subpleural and peripheral lung parenchyma. The inflammation is accompanied by peribronchiolar fibrosis and bronchiolar metaplasia (Fig. 94.8A and B). There is ingrowth of bronchiolar epithelium along the alveolar ducts to alveoli through canal of Lambert. This process of bronchiolar metaplasia of alveolar lining is termed as “Lambertosis’ or “microscopic honeycomb change”. Bronchiolocentric interstitial pneumonia has histologic similarity to hypersensitivity



Figs 94.8A and B: (A) Bronchiolocentric interstitial pneumonia showing interstitial fibrosis and bronchiolar metaplasia of the adjoining alveolar spaces termed as lambertosis. (B) Higher power showing metaplastic bronchiolar epithelium in bronchiolocentric interstitial pneumonia

pneumonia with a higher degree of centrilobular fibrosis and absent granulomas. It can be hypothesised that BrIP represents chronic hypersensitivity pneumonia.

DRUG INDUCED INTERSTITIAL LUNG DISEASE (DIILD)

An increasing number of drugs are recognized to induce distinctive patterns of ILD, ranging from benign infiltrates to life-threatening adult respiratory distress syndromes. In addition to drugs, biomolecules such as proteins and cytokines, and medicinal plants are also capable of inducing respiratory disease. A list of drugs having the potential to cause pulmonary disease continues to grow and now at least 350 agents are recognized[14] (Table 94.2).

TABLE 94.2: Drugs known to cause interstitial lung disease

Anticonvulsant, anti-psychotic, antidepressant	Carbamazepine, Chlordiazepoxide, Fluoxetine Phenothiazines, Phenytoin
Anti-inflammatory	Aspirin, Gold, Methotrexate, Penicillamine
Antimetabolic	Azathioprine, Cytarabine, Fludarabine Gemcitabine, 6-Mercaptopurine
Antimicrobial	Amphotericin B, Ethambutol, Isoniazid Minocycline, Nitrofurantoin
Biologic response modifiers	Granulocyte-macrophage colony-stimulating factor, Interferon, Interleukin-2, Tumor necrosis factor
Cardiovascular	Amiodarone, Angiotensin-converting enzyme inhibitors, Anticoagulants
Chemotherapeutic and immunosuppressive	Bleomycin, Busulfan, Chlorambucil Cyclophosphamide, Cyclosporin A
Illicit drugs	Cocaine, Heroin, Methadone, Methylphenidate Narcotic and sedative drugs

A carefully obtained history that includes medications is essential in suspecting a drug-induced reaction. A major, but largely unresolved question is why, out of the treated population of patients, only some individuals will develop DI-ILD. Explanations for the unequal risks among patients include the following:

- Prior respiratory reactions to the drug, or to unrelated compounds
- Type of underlying disease for which the drug is being given. Diseases such as rheumatoid arthritis or ulcerative colitis may increase the relative risk of developing respiratory disease from disease modifying drugs
- Occupational factors, such as exposure to asbestos, may potentiate the noxious respiratory effects of ergot drugs
- Activation and detoxification pathways of drugs and chemicals, which differ quantitatively and qualitatively among individuals

Drug-induced pulmonary diseases can present in a variety of syndromes, clinical presentations and radiographic patterns. The most common presentations of drug-induced pulmonary disease are an abnormality on a chest radiograph or a symptom complex.

Clinicoradiological Patterns

The clinicoradiographical correlates of DI-ILD range from subclinical opacities to a picture of white lungs with the criteria of ARDS. In the patient with migratory opacities with or without chest pain that could be suggestive of organizing pneumonia, a careful drug history should be taken, as this clinical pattern may relate to exposure to drugs or radiation. Transient infiltrates have been described in mild form of DI-ILD.

Pathology

Reports of DI-ILD in which histological data were obtained indicate that drugs can induce many distinctive histopathological patterns of ILD.[15] Drugs can trigger the development of such conventional patterns of ILD as:

- Hypersensitivity pneumonia
- Mild eosinophilic pneumonia
- Nonspecific interstitial pneumonia (cellular or fibrotic)
- Usual interstitial pneumonia
- Organizing pneumonia (OP or BOOP)
- Desquamative Interstitial Pneumonia (DIP)

While some drugs (e.g. minocycline, nitrofurantoin) induce quite stereotyped reactions in the lung (eosinophilic pneumonia and the cellular type of nonspecific interstitial pneumonia, respectively) other drugs (e.g. amiodarone, bleomycin), can induce a palette of variegated histopathological patterns in different patients. Patterns described under the term "amiodarone pneumonitis" may include nonspecific interstitial pneumonia (cellular or fibrotic type), alveolar filling by foamy macrophages, organizing pneumonia, diffuse alveolar damage, interstitial lung fibrosis, a pattern of "usual interstitial pneumonia," or any combination thereof depending on the patient and, possibly, the site of the lung biopsy. A notable clue that suggests the drug as a cause is the fact that the ILD will demonstrate a relative refractoriness to steroids, or will recur while the patient is still receiving relatively high dosages of steroids. Early diagnosis is important, because stopping the drug usually reverses toxicity, whereas unrecognized toxicity can be progressive and even fatal. Diagnosis requires being alert and vigilant for adverse pulmonary reactions in the appropriate clinical settings.

CONNECTIVE TISSUE DISORDER ASSOCIATED INTERSTITIAL LUNG DISEASE

The Connective Tissue Disorders (CTDs) comprise a heterogeneous group of diseases including rheumatoid arthritis, systemic sclerosis, polymyositis/dermatomyositis (PM/DM), Systemic Lupus Erythematosus (SLE), Sjögren's syndrome and mixed connective tissue disorders. Pulmonary complications are commonly associated with connective tissue disorders and can affect various anatomical compartments of the lung (airways, vasculature, interstitium, pleura, etc.) either individually or in combination. The reported prevalence of clinically overt pulmonary parenchymal disease ranges from 30% in patients with PM/DM to 10% in patients with Sjögren's syndrome and 5% in those with rheumatoid arthritis and SLE.[16] In some occasions, the lung disease precedes the more typical systemic manifestations and the evolution of the pulmonary disease is independent from the systemic disease and is associated with greater mortality and morbidity.

Rheumatoid Arthritis Associated Interstitial Lung Disease (RA-ILD)

Rheumatoid Arthritis (RA) is a destructive, systemic, inflammatory disorder that is defined by its characteristic attack on diarthrodial joints. A major portion of RA's disease burden, including the excess mortality, appears to be due to its extra-articular manifestations and pulmonary complications are directly responsible for 10 to 20% of all mortality. The prevalence of ILD in rheumatoid varies depending on the criteria used to establish the diagnosis. Clinically, significant ILD has been described in approximately 7% of subjects, whereas autopsy studies have described a prevalence of up to 35%.[17] Histopathological patterns of ILD associated with RA include:

- Usual Interstitial Pneumonia (UIP)
- Nonspecific Interstitial Pneumonia (NSIP)
- Organizing Pneumonia (OP)
- Lymphocytic Interstitial Pneumonia (LIP)
- Diffuse alveolar damage
- Rheumatoid nodules

In RA, UIP pattern is more commonly seen on surgical lung biopsy than NSIP.[18] In RA-ILD, cellular inflammatory, fibrosing, and mixed changes are seen, and these pathologic patterns fully overlap with those seen in the idiopathic interstitial pneumonias. The information provided by these pathologic patterns is important predictor of early mortality, with patterns characterized by fibrosis (e.g. UIP, fibrosing NSIP) having a worse prognosis than those characterized by cellular disease (e.g. cellular NSIP). Park and colleagues supports the hypothesis that the prognosis of subjects with Collagen Vascular Disease (CVD)-ILD, and particularly those with

CVD-UIP, is better than that of patients with idiopathic UIP.

Hypothesis for the development of lung fibrosis in RA is that a cellular inflammatory process is required for initiation of secondary fibroproliferative process, and the fibroproliferative process may then become progressive and independent of its initiating cause. However, once the fibroproliferative process begins, the clinical course and gene expression profile become similar to those of IPF, the prototypical fibrosing lung disease, and the disease becomes unresponsive to immunosuppression. The presence and number of fibrotic foci have been shown to correlate with mortality. The presence of areas of lymphoplasmacytic infiltrate is associated with physiologic improvement in response to cyclophosphamide and corticosteroid therapy, whereas fibroblast foci and areas of airspace organization are associated with a decline in function.

Systemic Lupus Erythematosus (SLE)

Parenchymal lung lesions especially NSIP and LIP are more common in SLE as compared to extensive fibrotic lesions seen in other collagen vascular diseases. Less commonly, the pathological changes include alveolar hemorrhages with associated expansion and destruction of alveolar septa by capillaritis. In addition, variety of pulmonary vascular changes like intimal thickening, medial hypertrophy and periadventitial fibrosis have been reported.

Polymyositis/Dermatomyositis

Nonspecific interstitial pneumonia and organizing pneumonia are the most common pattern of ILD associated with PM/DM.

Sjögren’s Syndrome

Lymphocytic interstitial pneumonia and amyloidosis are the most common pattern of ILD associated with Sjögren’s syndrome.

HYPERSENSITIVITY PNEUMONITIS (HP)

Hypersensitivity pneumonitis also known as extrinsic allergic alveolitis is an interstitial lung disease caused by immunological response to inhalation of organic substances and certain inorganic chemicals. It is thought to result from combination of type III (immune complex) and type IV (cell mediated) immune reactions.[19] The main etiological agents include thermophilic bacteria, fungi and animal proteins. The most common occupation related HP is farmer’s lung followed by air conditioner lung, humidifier lung and pigeon breeder’s lung. Hypersensitivity pneumonitis may present in three forms: Acute, subacute and chronic depending upon the intensity and frequency of exposure. High resolution computed tomography findings include centrilobular nodular opacities and areas of ground glass attenuation.

Histopathological Features

The diagnostic features of HP include triad of patchy, nonspecific interstitial pneumonia with peribronchiolar attenuation, non-necrotizing granulomas and foci of bronchiolitis obliterans. The inflammatory infiltrate is composed of lymphocytes and plasma cells present around bronchioles and extending into alveolar septa. The granulomas are interstitial, poorly formed and composed of epithelioid histiocytes and Langhans’ giant cells. In absence of granulomas the morphological changes can resemble cellular NSIP, thus requiring careful identification of specific antigen.

Treatment and Prognosis

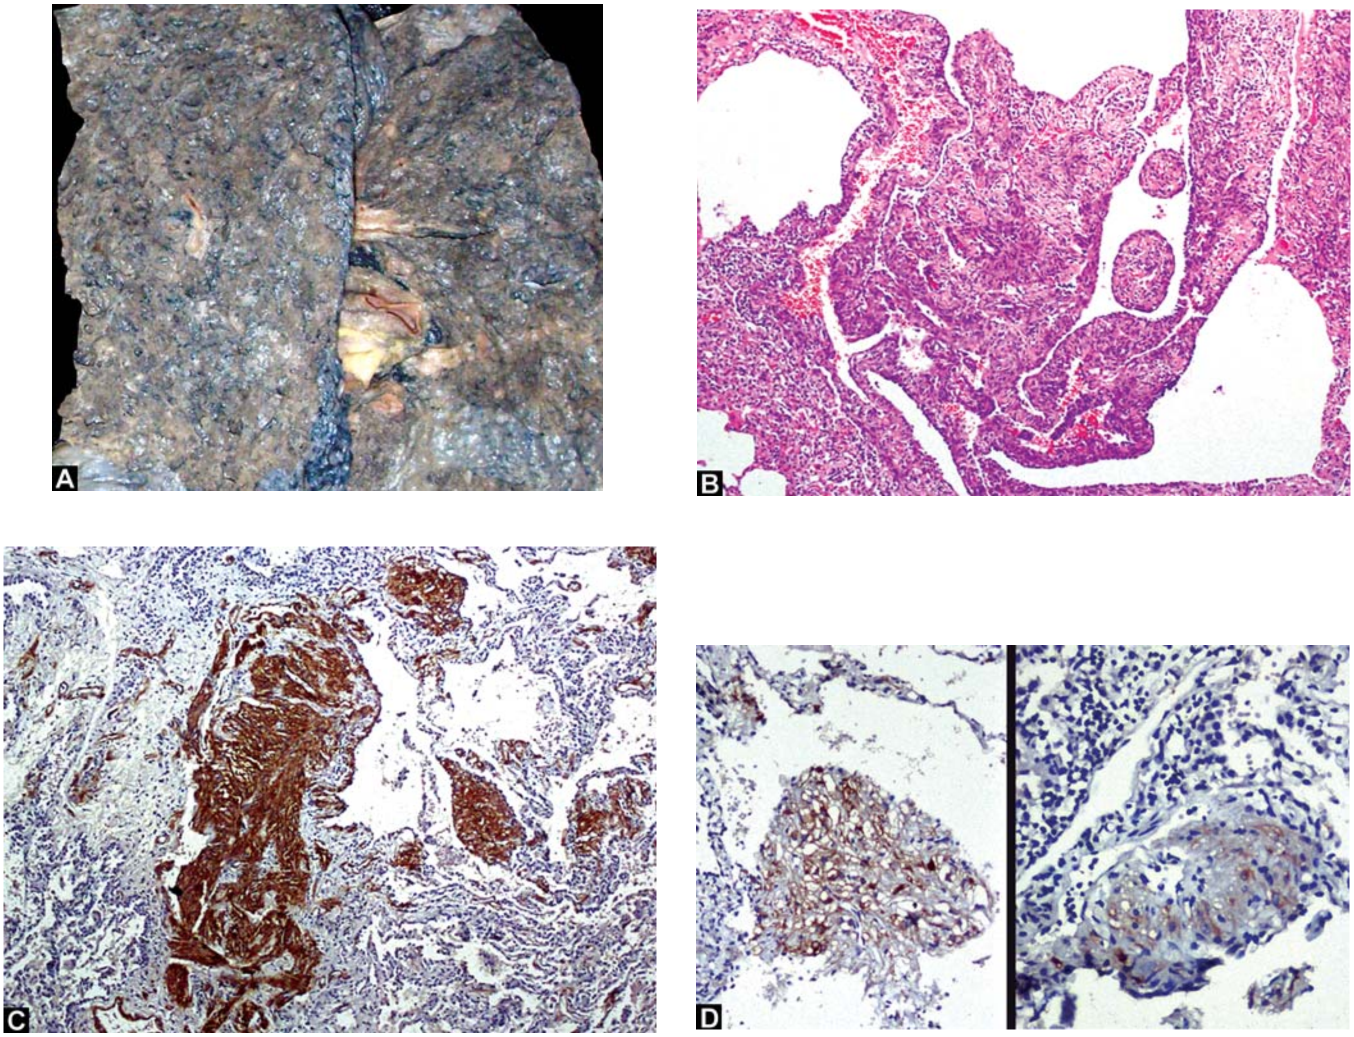
The therapeutic strategy for HP is avoidance of offending agent. The prognosis depends upon the amount and reversibility of damage.

LYMPHANGIOLEIOMYOMATOSIS (LAM)

Pulmonary lymphangioleiomyomatosis is a rare disease characterized by the haphazard proliferation of immature myoid cells throughout the interstitium of the lung. Lymphangioleiomyomatosis is currently classified by the World Health Organization under the broad group of tumors known as PEComas, derived from Perivascular Epithelioid Cells (PECs).[20] The PEC cells are perivascular cells with myoid features characterized by positivity for smooth muscle actin, HMB-45 and Melan A immunostains. It occurs exclusively in women during reproductive years of life, either sporadically or in association with tuberous sclerosis. Patients present with progressive dyspnea, chylous pleural effusions and recurrent pneumothoraces. Radiological examination shows diffuse reticular or reticulonodular shadows. Thin walled cystic spaces seen on HRCT are highly suggestive of LAM.

Histopathological Features

Gross appearance of lungs in LAM is characteristic and shows multiple air filled cysts (Fig. 94.9A).



Figs 94.9A to D: (A) Lymphangioleiomyomatosis; Gross showing innumerable cysts throughout the lung. (B) Varying proliferation of immature smooth muscle cells in the walls of cystic spaces. (C) Smooth muscle cells positive for smooth muscle actin. (D) Smooth muscle cells positive for Melan A and HMB45 immunostains

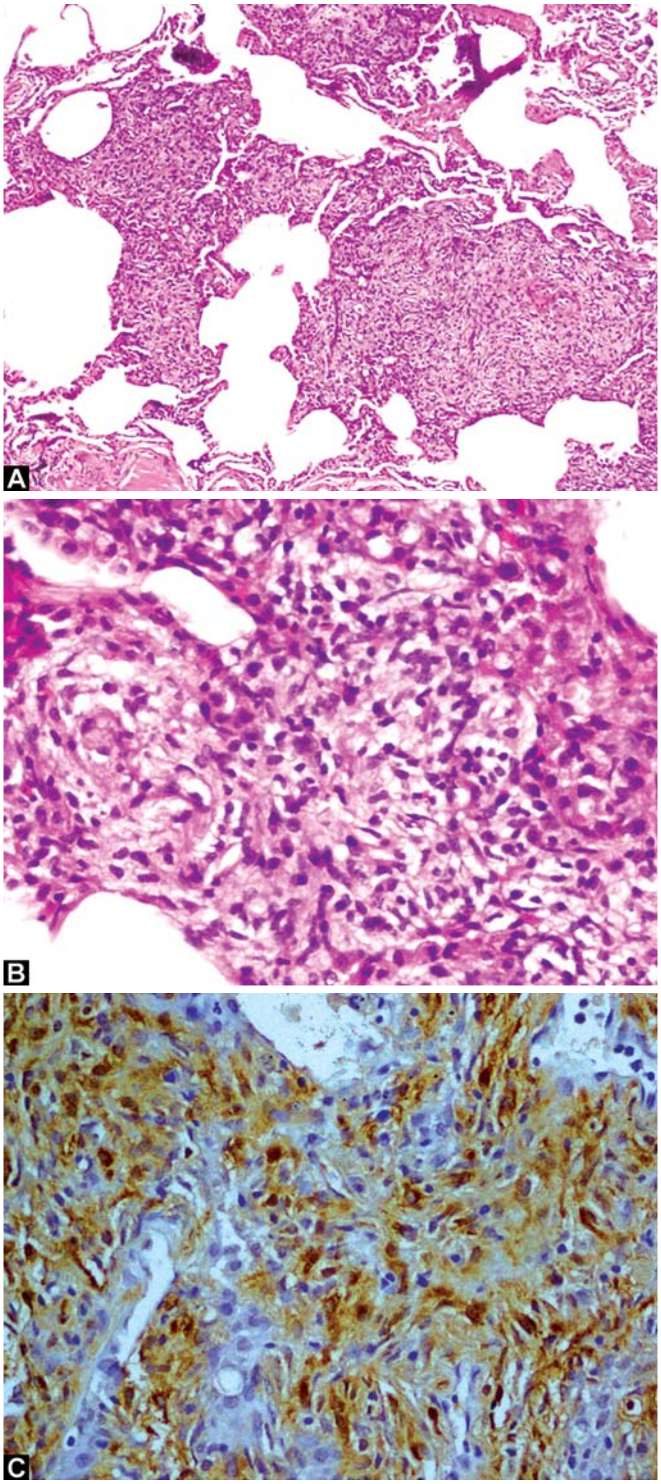
Microscopically, cystic change is the striking feature. There is randomly distributed proliferation of immature smooth muscle cells in the interstitium (Fig. 94.9B), around bronchioles, blood vessels, lymphatics, alveolar septa and walls of cystic spaces. These myoid cells are positive for smooth muscle actin (Fig. 94.9C), HMB-45 and Melan A (Fig. 94.9D).

PULMONARY LANGERHANS CELL HISTIOCYTOSIS (LCH)

Pulmonary langerhans cell histiocytosis, also known as pulmonary eosinophilic granuloma and pulmonary histiocytosis X is characterized by abnormal proliferation of Langerhans cells. Langerhans cells are dendritic or antigen presenting cells of the body that express CD1a, langerin and S-100 protein.[21] Pulmonary LCH has been linked to cigarette smoking. Experimental studies have shown increased number of dendritic cells in lungs chronically exposed to cigarette smoke.[22,23] The most common presenting symptoms include dyspnea, cough, chest pain, fever and hemoptysis.

Histopathological Features

Grossly lung parenchyma shows well demarcated grayish white nodules of 1 to 2 cm in maximum dimension. In chronic phases, there is pulmonary fibrosis, cystic change and honeycombing. The characteristic microscopic feature is nodular aggregates of Langerhans cells (Fig. 94.10A). These cells have pale convoluted nuclei with small nucleoli, pale eosinophilic cytoplasm and ill defined cell borders (Fig. 94.10B). These cells are associated with other inflammatory cells like lymphocytes, plasma cells and eosinophils. These Langerhans cells are positive for S-100 (Fig. 94.10C) and CD1a immunostains. The adjacent lung parenchyma shows interstitial fibrosis and alveolar cell hyperplasia. With the evolution of disease, fibrosis evolves and cellular nodules are replaced by stellate fibrous nodules.



Figs 94.10A to C: (A) Nodules of Langerhans cell histiocytosis admixed with other inflammatory cells. (B) High power showing Langerhans cells with pale nuclear chromatin and convoluted nuclear membranes admixed with lymphocytes and plasma cells. (C) S-100 immunostain highlighting Langerhans histiocytes

Idiopathic Interstitial Pneumonias

H Shigemitsu, Ngozi Orjioke

INTRODUCTION

The pulmonary interstitium is defined as the loose connective tissue surrounding the lungs. It consists of alveolar epithelium, pulmonary capillary endothelium, basement membrane, and perivascular and perilymphatic tissues. Idiopathic Interstitial Pneumonias (IIPs) is a condition in which the interstitium is replaced with the extracellular matrix and inflammatory cells resulting in impaired gas exchange. As the name suggests, the IIPs is a heterogeneous group of diseases of unknown etiology that share some common clinical features and are distinguished primarily by radiography and histopathology. This distinction is important as it impacts therapeutic options and prognosis.

EPIDEMIOLOGY

Among the IIPs, Idiopathic Pulmonary Fibrosis (IPF) is the most commonly described with annual incidence in the US estimated at 6.8 to 16.3 per 1,00,000 and a prevalence of 14.0 to 42.7 per 1,00,000.[1] Nearly two-third of the patients are predominantly men above 60 years of age. Reports from India suggests that there is a trend towards higher incidence of IPF with advancing age; however age at presentation is almost a decade earlier.[2]

CLASSIFICATION

Based on the ATS/ERS consensus statement,[3] IIPs are classified under the umbrella of Diffuse Parenchymal Lung Diseases (DPLDs). Idiopathic interstitial pneumonias are further subclassified into: Idiopathic Pulmonary Fibrosis (IPF)/Cryptogenic Fibrosing Alveolitis (CFA) and IIPs other than IPF.

The latter includes the following six histologic subtypes:

1. Nonspecific Interstitial Pneumonia (NSIP)
2. Cryptogenic Organizing Pneumonia (COP)
3. Respiratory Bronchiolitis-associated Interstitial Lung Disease (RB-ILD)
4. Desquamative Interstitial Pneumonia (DIP)
5. Acute Interstitial Pneumonia (AIP)
6. Lymphoid Interstitial Pneumonia (LIP)

Although this classification is mainly based on the histologic patterns, the clinical and radiological features correlate well with the associated pathology.

CLINICAL FEATURES

It has increasingly been recognized that the diagnosis of IIPs require an interdisciplinary approach between the clinicians, radiologists and the pathologists. The signs and symptoms are usually nonspecific, but referable to the pulmonary system (Table 95.1).[1-4] Nonproductive cough and progressive dyspnea with exertion usually prompts the patient to seek medical attention. The onset and progression can be variable, thus a detailed history of the onset of symptoms, symptom duration and associated features must be obtained. Furthermore, particular attention should be paid to obtain detailed history of tobacco use; family history of lung disease especially with pulmonary fibrosis and to the current and prior drug use to rule out medication induced lung fibrosis. Occupational exposure history with attention to duration, degree and latency of exposure must also be carefully elucidated. In the developing countries where expensive diagnostic

TABLE 95.1: Summary of clinical features of IIPs

Diagnosis	*Features*	*PFTS*	*BAL*	*Histological pattern*	*Treatment*	*Prognosis*
IPF	Gradual onset, mostly men >50 year. Constitutional symptoms are unusual.	Restrictive pattern, decrease DLCO, low resting PaO_2	Neutrophilic predominant with mild or moderate increase in eosinophils usually <20%	UIP	Ineffective, Lung transplantation	Mortality 50–70% in 5 years
NSIP	Mean age 40-50 year, no sexual predominance, no association with smoking. Gradual onset. Constitutional symptoms may be present.	Restrictive, mild airflow limitation in minority, reduced DLCO, hypoxemia on exercise	Lymphocytic predominant	**NSIP** Cellular pattern, fibrosing pattern	Corticosteroids	Mortality <10% in 5 years
COP	Mean age 55 year Equal sex distribution. Cough may be productive. Nonsmokers outnumber smokers. Constitutional symptoms Laboratory findings include neutrophilia with elevated ESR/CRP	Restrictive, mild airflow limitation reduced DLCO, mild resting hypoxemia	Lymphocyte predominant with ratio of $CD4^+$ to $CD8^+$ is decreased.	OP	Corticosteroids	Complete recovery >65%, Relapses in many mortality rare
RB-ILD	Rarely symptomatic Nonspecific respiratory symptoms 40–50 years Current smokers	Obstructive/restrictive patterns Mild to moderate decrease in DLCO Isolated increase in RV	Modest increase in neutrophils Alveolar macrophages with black pigmented inclusions	RB	Smoking cessation	Mortality rare
AIP	Acute Rapidly progressive Prior illness suggestive of viral URI Mean age 50 year No gender predilection Not associated with smoking	Restrictive pattern Decreased DLCO Hypoxemia	Increased total cells, hemorrhage, atypical pneumocytes, fragments of hyaline membrane	DAD	No proven treatment	Mortality >50% within 1–2 months
DIP	Insidious 40–50 year Smokers Digital clubbing in 50% M:F 2:1	Normal or Restrictive pattern Decreased DLCO	Modest increase in neutrophils/eosinophils and lymphocytes. Alveolar macrophages with black pigmented inclusions	DIP	Smoking cessation	Mortality rate 5% in 5 years
LIP	F>M 50 years Insidious Constitutional symptoms +/– adenopathy Mild anemia Monoclonal increase in IgG or IgM in 75%		Lymphocytes without clonality on immunophenotyping	LIP	Corticosteroids	Not well characterized

AIP: Acute interstitial pneumonia; BAL: Bronchoalveolar lavage; COP: Cryptogenic fibrosing alveolitis; DAD: Diffuse alveolar damage; DIP: Desquamative interstitial pneumonia; IPF: Idiopathic pulmonary fibrosis; LIP: Lymphoid interstitial pneumonia; NSIP: Nonspecific interstitial pneumonia; OP: Organizing pneumonia; PFTS: Pulmonary function tests; RB-ILD: Respiratory bronchiolitis-associated interstitial lung disease; UIP: Usual interstitial pneumonia

TABLE 95.2: Radiographic features of IIPs

Clinical diagnosis	*Radiographic features*	*CT distribution*	*CT findings*
IPF/CFA	Reticular Basilar Low lung volumes	Peripheral Subpleural/basal	Architectural distortion Honeycombing Traction bronchiectasis Focal ground glass
NSIP	Reticular	Peripheral Subpleural/basal Symmetric	Ground glass Consolidation Irregular lines
COP	Patchy bilateral consolidations	Subpleural/peribronchial Lower zone predominant	Patchy consolidation Nodules
AIP	Progressive diffuse consolidation	Diffuse	Consolidation Ground-glass with lobular sparing Traction bronchiectasis (late)
DIP	Ground glass opacity	Peripheral Lower zone	Reticular lines Nodular texture to ground glass opacification Honeycombing <1/3 of cases
RB-ILD	Ground-glass Bronchial wall thickening	Diffuse	Patchy ground glass Bronchial wall thickening Centrilobular nodules
LIP	Reticulonodular	Diffuse	Ground glass Septal/bronchovascular thickening Centrilobular nodules Thin-walled cysts

AIP = Acute interstitial pneumonia; CFP= Cryptogenic fibrosing alveolitis; COP = Cryptogenic organizing pneumonia; DAD = Diffuse alveolar damage; DIP = Desquamative interstitial pneumonia; IPF= Idiopathic pulmonary fibrosis; LIP= Lymphoid interstitial pneumonia; NSIP= Non-specific interstitial pneumonia; RBILD= Respiratory bronchiolitis-associated interstitial lung disease; UIP = Usual interstitial pneumonia.

equipment and surgical personnel may not be readily available, such detailed history in combination with the clinical features and radiographic features (Table 95.2), may help direct the diagnostic approach and rule out other diseases in the differential diagnosis.[4]

When the clinicoradiological features are atypical of IPF, a diagnosis of idiopathic interstitial pneumonia, that is not IPF, is made.[3] At this time lung tissue, obtained by surgical biopsy or Bronchoalveolar Lavage (BAL) with Transbronchial Biopsy (TBBx) based on available modalities to evaluate the histopathology, is essential in the diagnostic algorithm (Fig. 95.1). Laboratory tests for autoimmune disease, vasculitides and immunological response to organic inhalational exposure may assist in directing the clinician to various etiologies that are known to cause IIPs. However, routine laboratory investigations usually play no significant role in the diagnostic process.

HISTOLOGICAL FEATURES

Histopathological examination of the lung is the gold standard in confirming the diagnosis. The patterns observed have been shown to correlate with the clinical course and response to treatment. In IPF, the characteristic injury pattern is Usual Interstitial Pneumonia (UIP). The hallmark of UIP is fibroblastic foci which consist of dense eosinophilic fibrosis with scattered foci of young myxoid fibrosis and fibroblasts. These foci represent the advancing or progressive edge of the disease and are required to be a major component of the histological pattern for a confident diagnosis. The injury

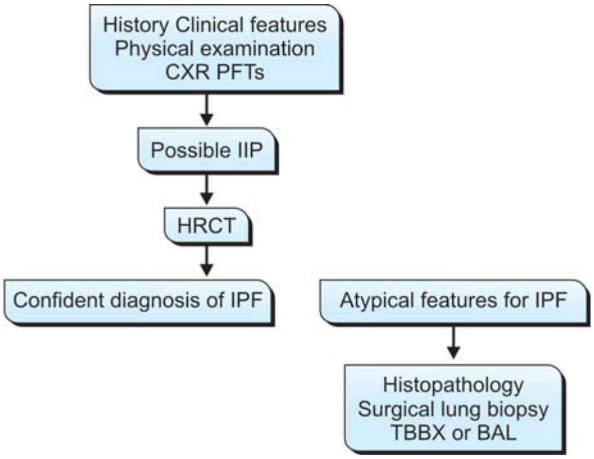

Fig. 95.1: Simplified algorithm for diagnosis of idiopathic interstitial pneumonias

is predominantly seen in the subpleural region and consists of a pattern of temporal heterogeneity.[2,3] In other words, the areas of injury with fibroblastic foci and honeycomb changes are seen adjacent to relatively unaffected tissue. Other histological patterns of IIPs are summarized in Table 95.3.

TREATMENT

Management usually involves supportive therapy with oxygen supplementation, immunizations and treatment of any intercurrent infections and management of complications that may arise from treatment.[5] For the majority of IIPs, the mainstay of treatment is corticosteroids. Other treatments options, including immunosuppressive therapies and antifibrotic agents, are discussed individually.

IDIOPATHIC PULMONARY FIBROSIS (IPF)

Epidemiology

Idiopathic pulmonary fibrosis, also known as cryptogenic fibrosing alveolitis, is a distinctive type of chronic fibrosing interstitial pneumonitis of unknown etiology accounting for over 50% of all IIPs. It is associated with

TABLE 95.3: Histological patterns in the IIPs

Diagnosis	*Histological pattern*	*Description*
IPF	Usual interstitial pneumonia	Patchy/focal involvement of the lung: dense fibrosis and honeycombing with areas of “normal lung” adjacent to heavily involved areas.Subpleural distribution, paraseptal and peribronchiolar. Fibrosis, temporal heterogeneity. Alveolar component reduced or completely lost in affected areas. Bronchiolar component damage and abnormal regeneration
NSIP	Non-specific interstitial pneumonitis	**Cellular pattern:** Homogenous interstitial chronic inflammatory infiltrate focal alveolar collections of macrophages. Focal alveolar damage with pneumocyte type II hyperplasia and organizing pneumonia **Fibrosing pattern:** Dense or loose interstitial fibrosis with homogeneous involvement of the lung. Mild inflammatory infiltrate. No evidence of fibroblast foci or honeycombing.
COP	Organizing pneumonia	Organizing tissue (polyps) within alveolar ducts and alveoli. Mild interstitial inflammatory infiltrate/intra-alveolar foamy macrophages. Focal alveolar damage with pneumocyte type II hyperplasia. Preservation of lung structure, the process appears mainly centered on small airways.
RB-ILD	Respiratory bronchiolitis	Bronchiolocentric alveolar macrophage accumulation. Mild bronchiolar fibrosis and chronic inflammation. Macrophages have dusty brown cytoplasm (may be positive for iron stains)
AIP	Diffuse alveolar damage	Diffuse involvement of the lung parenchyma. Fibrosis of uniform temporal appearance with myofibroblast accumulation within alveolar interstitial spaces. Diffuse features of acute alveolar damage with pneumocyte type II hyperplasia, atypia and hyaline membranes.
DIP	Diffuse interstitial pneumonitis	Chronic interstitial inflammation and numerous intra-alveolar mononuclear cells, macrophages. Diffuse alveolar mononuclear cell (macrophage) accumulation. Cuboidal epithelial cells (type 2 cells) line alveoli. Mild diffuse interstitial fibrosis and chronic inflammation. Occasional lymphoid follicles. No dense scarring or revamping of architecture
LIP	Lymphoid interstitial pneumonia	Intense and diffuse chronic accumulation of lymphocytes occurs in alveolar interstitial spaces. Follicular reaction may occur along lymphatic routes.

a surgical lung biopsy showing a UIP pattern. It is predominantly seen in middle-aged men with a median age of 66 years at time of diagnosis.[6] In a series from India, the age of presentation was a decade earlier.[4] The incidence is higher with the increasing age.[6]

Etiology

The cause of IPF is unclear, but it is increasingly becoming clear that it represents in part a response to injurious agent(s), which results in dysregulated inflammation and repair of the interstitium and alveolar epithelium. Eventually chronic inflammation and an imbalance in the production of various cytokines, growth factors and profibrotic agents result in inexorable fibrotic response with collagen deposition.[7] Thus, agents targeted at the cytokine release and processes implicated in the perpetuation of the pulmonary fibrosis and vascular remodeling are currently being investigated.

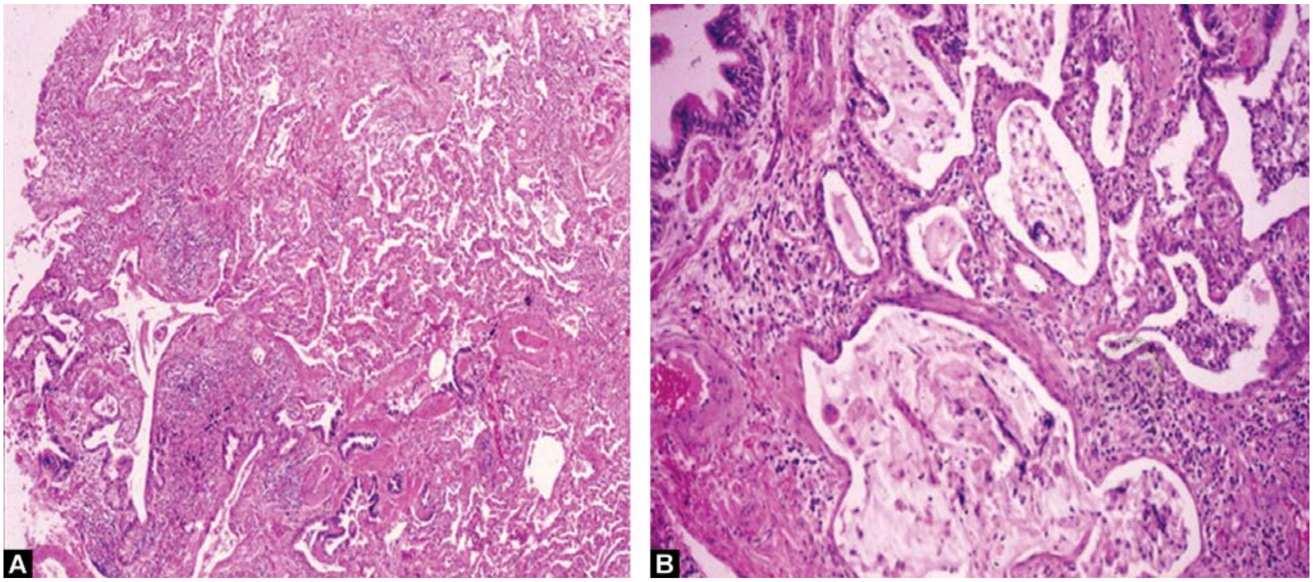
Signs and Symptoms

Paroxysmal nonproductive cough associated with the progressively worsening of shortness of breath are the most common symptoms. These symptoms have an insidious onset and are often present for months prior to the diagnosis.[6] End inspiratory crackles are present on lung examination, with finger clubbing in 25 to 50% of patients. In late stages of the disease, signs attributable to pulmonary hypertension or right heart failure may be present.

Diagnosis

The exclusion of any other interstitial lung disease based on history, physical examination and ancillary studies is the first step to making a diagnosis of IPF in the absence of an open-lung biopsy.[6] Idiopathic pulmonary fibrosis is characterized morphologically with a UIP pattern on pathology (Figs 95.2A and B). The findings on chest radiography, CT and gross pathological examination of lung with IPF/UIP is demonstrated in Figs 95.3A to C. The pulmonary function test usually reveals a restrictive physiology with abnormal gas exchange.[3] The typical chest radiographic features include diffuse peripheral reticular opacities with basilar predilection.[3,6] High Resolution Computed Tomograhy (HRCT) scan shows predominantly peripheral, subpleural, bibasilar reticular abnormalities; traction bronchiectasis and subpleural honeycombing. If ground-glass opacities appear to be the predominant radiographic finding, an alternate diagnosis other than IPF must be strongly considered.[2,8]

Clinical and radiographic findings well described that the American Thoracic Society (ATS) and European Respiratory Society (ERS) endorsed clinical criteria for a definitive diagnosis of IPF in the absence of a surgical lung biopsy (Table 95.4).[3] Specifically, radiological features with HRCT can be especially helpful in the diagnostic accuracy of IPF. This is useful in some developing countries where the option of rendering the diagnosis to a surgically obtained biopsy may not be readily available. However, if these typical features are



Figs 95.2A and B: UIP pattern on histopathology. Temporal heterogeneity and geographic heterogeneity. Patchy involvement of the lung with variation in the age of the fibrosis. Interstitial and alveolar inflammation, cellular proliferation and honeycombing cysts

TABLE 95.4: Diagnostic criteria of IPF/UIP in ATS/ERS criteria

DIAGNOSIS OF IPF IN THE ABSENCE OF SLB
Major criteria (All four must be present)

- Exclusion of other known causes of ILD such as drug toxicities, environmental exposuresand connective tissue diseases
- Abnormal pulmonary function studies that include evidence of restriction [reduced VC, often with an increased. Forced Expiratory Volume in One Second/Forced Vital Capacity (FEV_1/FVC) ratio] and impaired gas exchange [Increased P (A-a) O_2, decreased PaO_2] with rest or exercise or decreased. Diffusion lung capacity for carbon monoxide (DLCO)
- Bibasilar reticular abnormalities with minimal ground glass opacities on HRCT scans
- Transbronchial lung biopsy or BAL showing no features to support an alternative diagnosis

Minor criteria (Three or four must be present)

- Age >50 years
- Insidious onset of otherwise unexplained dyspnea on exertion
- Duration of illness >3 months
- Bibasilar, inspiratory crackles (dry or “Velcro” type in quality)

not present, a diagnosis of atypical IPF or other IIPs must be taken into consideration and a surgical lung biopsy may be necessary to confirm the diagnosis.

Treatment

Treatment is targeted at resolution and slowing down the progression of disease.[5,6,8] Corticosteroids[6,8] and immunosuppressive/cytotoxic agents such as azathioprine and cyclophosphamide,[6] have been the mainstay of treatment to date as recommended by the ATS/ERS consensus statement. However, there is a little evidence to support the use of these immunosuppressive therapies in IPF and thus the author believes this recommendation may change in the near future. As for the dosing, according to the ATS/ERS consensus statement, prednisone should be started at a dose of 0.5 mg/kg and tapered to a maintenance dose of 0.125 mg/kg. This should be combined with azathioprine or cyclophosphamide at a target dose of 2–3 mg/kg in carefully selected patients to spare the toxic effects of corticosteroids.

There is also evidence that the antioxidant N-acetylcysteine (NAC), at a dose of 600 mg three times a day, in combination with azathioprine and corticosteroids improves physiological parameters and may slow down progression of disease.[9] The rationale for NAC is based on the fact that NAC will replete the

glutathione levels and prevent oxidative injury that leads to fibroproliferation in IPF. Other antifibrotic agents, such as D-penicillamine and colchicine and pirfenidone, have been used alone or in combination.[5,8] A trial with pirfenidone was carried out in Japanese patients and found to be effective in stabilizing lung function and reducing the frequency of acute exacerbations.[10]

Clinical and physiological responses to therapy should be evaluated periodically at three to six months after the initiation of therapy to justify continuing the treatment. Supportive care with supplemental oxygen, immunizations, prompt treatment of infections and pulmonary rehabilitation helps to improve the quality of life.[5,8] In spite of theses therapies IPF portends a poor prognosis with a median five-year survival of less than 50%.[2,5] Lung transplantation becomes the only option for treatment for eligible patients, although this is not readily available in many developing countries.

Given the constraints and challenges in the developing world, Jindal et al. proposed a treatment protocol for IPF in developing countries (Fig. 95.4).[5]

Prognosis

The general clinical course is one of the progressive impairment of lung function resulting in respiratory failure. Patients often die from progression of the disease or as a result of complications of therapy, usually opportunistic infection.

Indicators for longer survival include younger age, female sex and early presentation with preserved lung function. Increased portion of lymphocytosis (20% to 25%) on BAL and a beneficial response or stable disease three to six months after the initiation of corticosteroid therapy[6,9] also appear to correlate with survival. As for younger patients with earlier onset, this appears to confer a more favorable response to therapy.[5]

NONSPECIFIC INTERSTITIAL PNEUMONIAS (NSIP)

Epidemiology

The mean age of onset is 40–50 years of age, which is about a decade earlier than in IPF, has been also reported in the pediatric population.[11] It occurs equally in both men and women, has no known association with cigarette smoking.[12]

Etiology

Unlike IPF, the etiology of NSIP may be more evident with autoimmune diseases, hypersensitivity pneumonitis and certain inhalational exposure. Therefore a diagnosis of NSIP should prompt clinical evaluation for an underlying etiology. However, the etiology in a significant number of patients with NSIP remains elusive and coined as idiopathic NSIP which has unique features from other forms of NSIP.

Signs and Symptoms

Onset is gradual and some patients have associated constitutional symptoms such as fever and weight loss in addition to respiratory symptoms such as chronic cough and dyspnea.[3] Finger clubbing is less common than in IPF, can occur in 10 to 35% of patients.[12] Inspiratory crackles are usually present on lung examination.

Diagnosis

Clinical features in the presence of a restrictive pattern and a reduction in DLCO suggest the diagnosis of an interstitial pulmonary disease. Histologically, NSIP can be further separated into cellular and fibrotic NSIP. In cellular NSIP, mild-to-moderate homogenous interstitial chronic inflammation is the predominant feature, unlike fibrosing NSIP where uniformly dense fibrosis is a prominent feature.[11] Temporal uniformity, the paucity of fibroblastic foci and honeycomb lesions are the features that histologically differentiate NSIP from UIP.[3] Radiographically, cellular NSIP in contrary to IPF show diffuse symmetric interstitial infiltrates and ground-glass opacities. In fibrotic NSIP, the radiographic signs of fibrotic disease are seen in some cases similarly to IPF.

Treatment/Prognosis

Katzenstein classified NSIP into three subgroups based on the degree of inflammation and fibrosis on histopathology: Group 1 primarily has interstitial fibrosis; group 2 inflammation and fibrosis; and group 3 primarily fibrosis.[11] Patients with cellular NSIP usually respond well to corticosteroids unlike fibrotic NSIP.[3] Thus the prognosis is good in cellular NSIP, as opposed to fibrotic NSIP, which has been shown to mirror that of IPF, given the similarities in histology and clinical features.

DESQUAMATIVE INTERSTITIAL PNEUMONIA (DIP)

Epidemiology

Desquamative interstitial pneumonia is a rare IIP primarily seen in smokers in the fourth to fifth decade of life.[13,14] The term DIP was coined by Myers et al. based on findings in six patients who had interstitial pattern on chest radiograph with restrictive pulmonary function test and respiratory bronchiolitis on histopathology.[15]

Etiology

In at-risk patients, tobacco induces injury to the bronchiolar and alveolar epithelium. The pathobiology is not completely understood as to why and how this occurs.[16] As in patients with pulmonary Langerhans cell histiocytosis, abnormal T-cell proliferation and increased secretion of peptides has been described.[16] It is likely that this disorder, like other cigarette smoking related lung diseases, occurs in susceptible individuals following initial injury to the pulmonary epithelium.

Signs and Symptoms

Dyspnea at rest or on exertion is the most common presenting symptom.[13] Onset is insidious. Cough may be dry or productive of nonpurulent sputum.[13] Systemic symptoms are usually absent with digital clubbing in some patients.[3] Physical examination shows crackles in less than 50% of patients.[3,13]

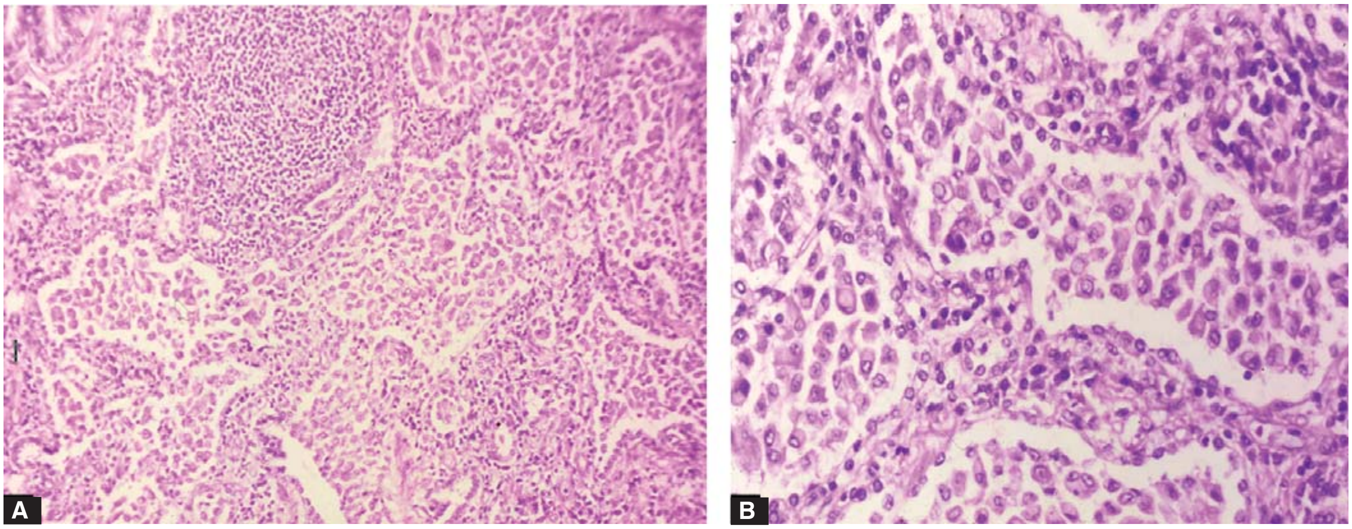
Diagnosis

The diagnosis should be suspected when these clinical and epidemiological features are seen in combination with radiographic findings.[3] Typical radiographic findings include patchy ground glass opacification with a predilection for the lower zones, though in rare cases it can even be normal.[16] The PFTs can show a combined obstructive and restrictive defect, often with a decrease in DLCO.[3,15]

The histological pattern is characterized by chronic interstitial inflammation and numerous intra-alveolar mononuclear cells, thought to be desquamated epithelial cells (hence the name) but subsequently proved to be macrophages (Figs 95.5A and B).[17]

Treatment

There is reported clinical response to smoking cessation alone or in combination with corticosteroid therapy.[3,14] In some cases, in spite of clinical stability, abnormal radiographic features may persist.[14]



Figs 95.5A and B: DIP pattern on histopathology. Diffuse macrophage accumulation with type 2 cells lining alveoli. Mild interstitial fibrosis, chronic inflammation and no dense scarring or architectural distortion is seen

Prognosis

Treatment outcomes are generally good. Some patients however have persistent disease despite smoking cessation; corticosteroid therapy may be useful in these cases.[14]

RESPIRATORY BRONCHIOLITIS-ASSOCIATED INTERSTITIAL LUNG DISEASE (RB-ILD)

Epidemiology

Recent studies have linked idiopathic DIP to Respiratory Bronchiolitis (RB) and RB-ILD in a spectrum of smoking related lung injury.[17]

It is considered a variant of DIP and has a patchy distribution rather than a diffuse process. Smokers in the third to fourth decade of life are usually affected.[18]

Signs and Symptoms

Most patients are asymptomatic or have mild symptoms of dyspnea and cough of insidious onset.[3,13,14] Inspiratory crackles are present on lung examination with digital clubbing in up to 25% in one series.[14]

Diagnosis

On spirometry, a combined defect with abnormalities of gas exchange is often seen.[3,17] Ground glass opacities and attenuation may be seen on chest imaging, associated with thickening of walls of central and peripheral airways. These findings are ultimately associated with the pathological lesion of respiratory bronchiolitis (Figs 95.6A and B).

Treatment

The only proven therapy for RB-ILD is smoking cessation. Only those who continue to be symptomatic in spite of smoking cessation should be considered for corticosteroid therapy.[3,16]

Prognosis

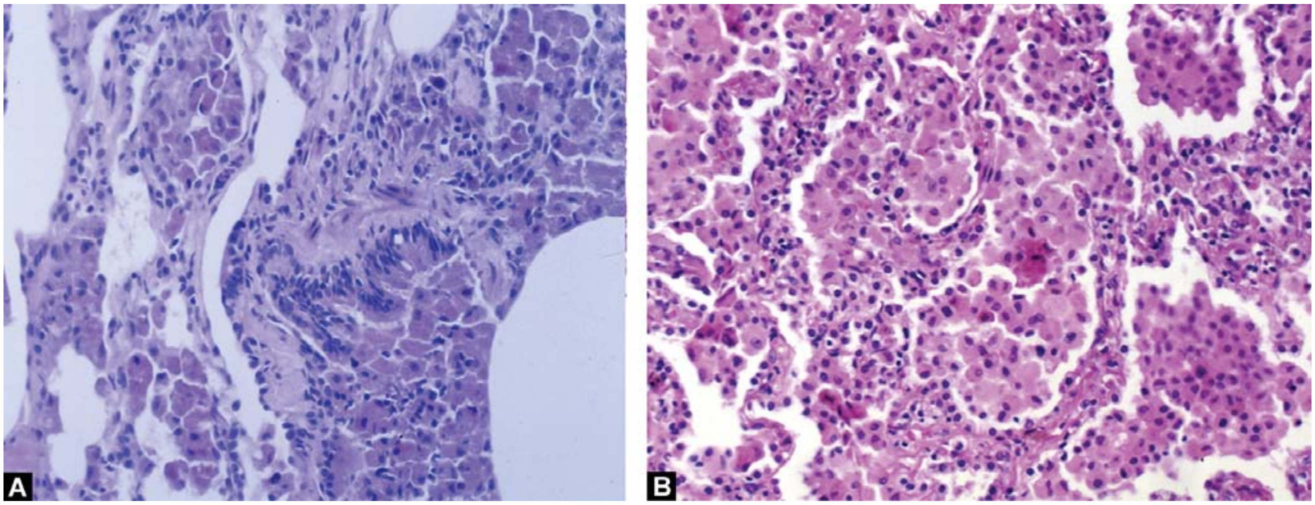
Prognosis is good and patients usually improve with smoking cessation. To date there are no documented cases of respiratory failure or death directly attributable to RB-ILD.[3,16]

CRYPTOGENIC ORGANIZING PNEUMONIA (COP)

Epidemiology

Cryptogenic organizing pneumonia, previously known as Bronchiolitis Obliterans with Organizing Pneumonia (BOOP), often presents clinically as a flu-like illness of subacute onset (weeks to a few months). The disease process was initially described by Grinblat and colleagues in two patients.[19] Organizing pneumonia is often a non-specific response to lung injury and is classified as cryptogenic when an underlying disease cannot be identified.

Cryptogenic organizing pneumonia is commonly diagnosed during the fifth decade of life; there have been case reports in adolescence.[20] In most series from



Figs 95.6A and B: RB-ILD pattern on histopathology. Clusters of dusty brown macrophages in respiratory bronchioles, alveolar ducts and peribronchiolar alveolar spaces are seen in RB-ILD

developing countries including data from the Middle East[21,22] and Southeast Asia,[23] there is no correlation between smoking status and the disease. Men and women are affected equally.

Etiology

Organizing pneumonia is a non-specific response of the lung to injury. It is termed cryptogenic when an inciting agent or disease process is absent. Increased expression of interleukin-8 and fibronectin genes by alveolar macrophages has been described in COP.[24] This suggests that the lung injury and inflammation may be initiated and perpetuated by inflammatory cytokines produced in situ by alveolar macrophages.[24] In mice models, there is a suggestion that genetic host factors play an important role in the development of lung fibrosis in COP.[24]

Signs and Symptoms

Cryptogenic organizing pneumonia often presents clinically as a flu-like illness of subacute onset (weeks to a few months).[3] Fever, dry cough with malaise, anorexia and weight loss are often present with mild dyspnea, especially on exertion.[3] Physical findings are sparse, with inspiratory crackles being present on lung examination.[3]

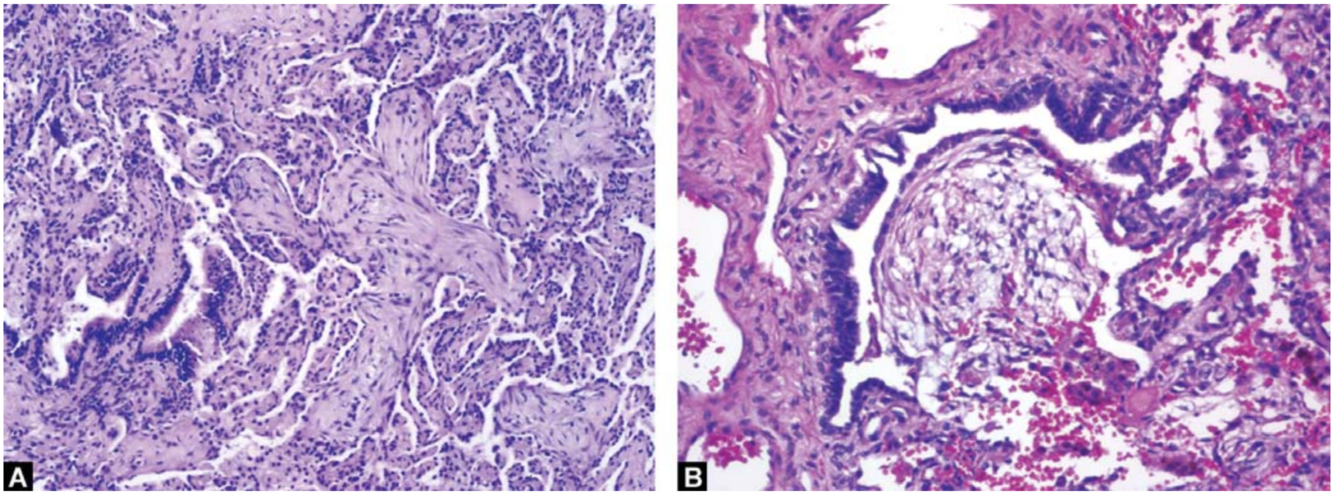
Diagnosis

The diagnosis should be considered in patients with features of a nonresolving pneumonia. Chest X-ray shows patchy migratory unilateral or bilateral airspace disease with predominantly peripheral distribution.[3] On CT scan, the opacities range from ground glass to dense consolidation. Though these radiographic findings are typical, they can be seen in other conditions.[24] Less commonly, radiographic features of diffuse interstitial opacities and solitary focal lesions may be seen.[24] Spirometry may be normal; however it typically reveals a restrictive pattern with some gas exchange abnormalities. In smokers, there may be an obstructive component to pulmonary function tests. Buds of granulation tissue are found within the lumen of the distal airways on histology (Masson bodies). This pattern is nonspecific and reflects an inflammatory response to lung injury. There is a preservation of lung architecture with the absence of scarring or honeycombing on histopathology (Figs 95.7A and B).[3]

Treatment/Prognosis

Most patients respond well to corticosteroids, but relapses can occur requiring chronic steroid therapy.[3] Cytotoxic drugs and steroid sparing agents are used in addition to corticosteroid where there is slow response to steroids alone.[24] A small group (10 to 15%) may progress to pulmonary fibrosis.[3] Factors that may predict poor outcomes include the lack of lymphocytosis on BAL, predominantly interstitial pattern on imaging and histological features of scarring and remodeling of lung parenchyma.[24]

Polypoid plugs of fibrous tissue (Masson bodies) within bronchiolar lumens, alveolar ducts and alveoli. Clusters of alveolar foamy macrophages are also present.



Figs 95.7A and B: Cryptogenic organizing pneumonia pattern on histopathology

ACUTE INTERSTITIAL PNEUMONIA (AIP)

Epidemiology

Hamman-Rich described a series of four patients who died from rapidly progressive lung disease, associated with respiratory failure and death within a few months of onset. Autopsy was characterized by a diffuse interstitial pneumonia and fibrosis.[25] Acute interstitial pneumonia is a rare and often fatal disease encountered in apparently healthy individuals after an acute respiratory illness and characterized by diffuse alveolar damage.[25] The syndrome mimics Acute Respiratory Distress Syndrome (ARDS).

Etiology

The exact mechanism responsible for AIP are poorly understood;[26] however there is diffuse acute lung injury resulting in acute respiratory failure. Several mediators have been described and implicated in this process. Proinflammatory, anti-inflammatory, metalloproteinases and proteins regulating apoptosis have all been implicated.[27-29]

Signs and Symptoms

The presentation is similar to that of ARDS. The onset is acute and often preceded by the symptoms suggestive of a viral upper respiratory tract infection followed by widespread pneumonia. Hypoxemia develops early followed by respiratory failure requiring mechanical ventilatory support. There is no association with smoking.[3]

Diagnosis

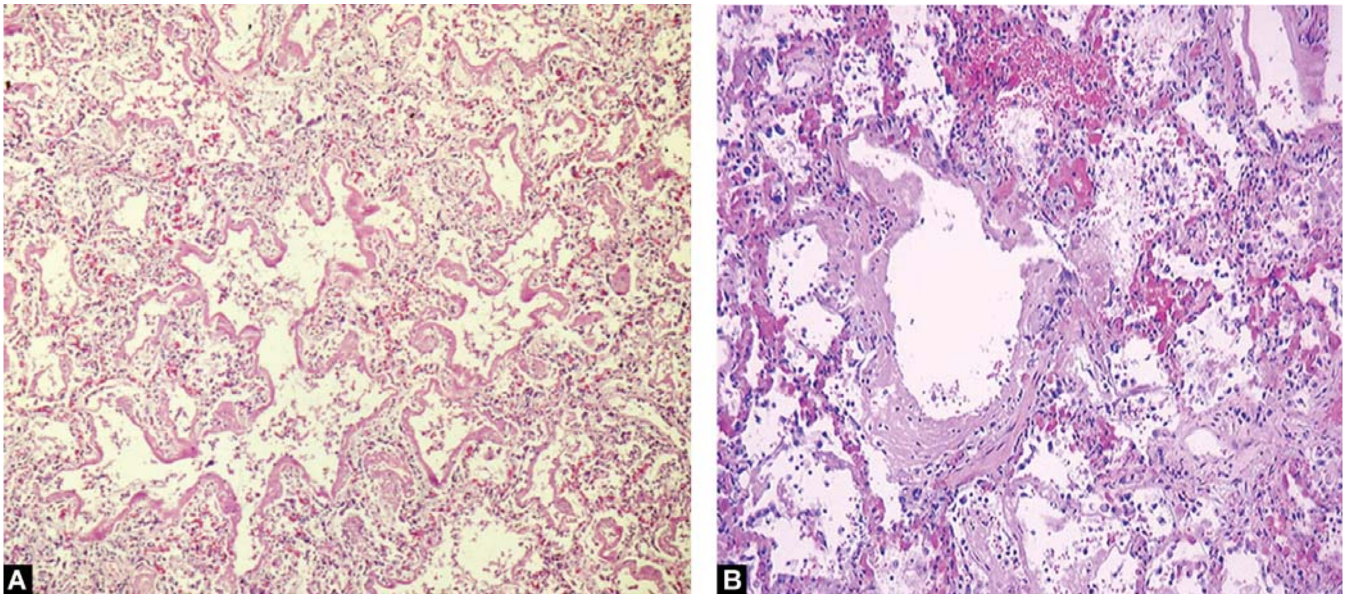
Based on the American Thoracic Society/European Respiratory Society guidelines[3] the criteria include rapidly progressive clinical course (less than 2 months) leading to respiratory failure; exclusion of infectious, toxic, autoimmune or any other cause of ARDS; Diffuse Alveolar Damage (DAD) on biopsy specimens; radiological findings consistent with ILD; and absence of chronic lung disease.[2] Bilateral airspace disease seen radiographically correlates with DAD seen on histology (Figs 95.8A and B).

Treatment

Since there is no proven treatment, supportive care with oxygen supplementation and mechanical ventilation is indicated. Early corticosteroid therapy and combination therapy with intravenous cyclophosphamide and vincristine have been reported.[30] Newer agents, such as inhaled nitric oxide, anticytokine antibodies and surfactant, may be useful.[31,32] There is a report of single lung transplantation as therapy for AIP.[33]

Prognosis

Mortality is greater than 60%.[3,26] Based on the morphology of lung parenchyma on CT, some authors report that this may help differentiate fulminant forms of AIP.[34,35] Those who survive may have no residual lung damage or residual pulmonary fibrosis.



Figs 95.8A and B: Acute interstitial pneumonia pattern on histopathology. Hyaline membranes with eosinophilic material lining alveolar spaces consistent with DAD are present with areas of progressive fibrosis

LYMPHOID INTERSTITIAL PNEUMONIA (LIP)

Epidemiology

One of the rarest of the IIPs, LIP mostly affects women in the fifth decade of life but can occur at any age.[3,26] Although part of IIPs, there is a thought that LIP possibly represents a lymphoproliferative disorder confined to the lungs that was initially described by Liebow and Carrington.[36] Lymphoid interstitial pneumonia has also been described in developing countries such as Africa and the Caribbean, but all in association with systemic diseases, most notably Human Immunodeficiency Virus (HIV) infection [or Acquired Immunodeficiency Syndrome (AIDS)] although some cases remain idiopathic. It has also been described in post bone marrow transplantation.[37]

Etiology

There is some evidence that this is a lymphoproliferative disorder rather than a primary interstitial pulmonary process.[38] It may result from a lymphoproliferative response to chronically presented viral antigens or cytokines with or without recruitment of circulating lymphocytes. Mutations of the B-cell CLL/lymphoma 6 gene have been associated with LIP.[38]

Signs and Symptoms

It is slow in onset with increasing cough and breathlessness. Constitutional symptoms, such as fever, weight loss, arthralgias, may be prominent features.[3] Chest examination often reveals bibasilar crackles with digital clubbing being rare.[39] Dysproteinemia with an isolated increase in IgG or IgM may be present in 75% of cases.[3]

Diagnosis

Chest X-ray may show an alveolar pattern predominantly at the bases or a diffuse disease with honeycombing. The predominant cell type on BAL is lymphocyte with a restrictive pattern on lung function tests. Histology reveals dense interstitial lymphoid infiltrate. This pathological finding has been described in other connective tissue disorders, such that the diagnosis can only be made once underlying connective tissue or systemic diseases have been excluded.[3]

Treatment

Some patients improve spontaneously without any treatment. Clinical improvement to corticosteroid therapy has been reported. In some cases, cytotoxic agents including cyclophosphamide, azathioprine and cyclosporine have been used.[38] Supplemental oxygen therapy and treatment of pulmonary infections may be necessary.

Prognosis

Survival is impaired; however mortality data are sparse because of the rarity of the condition.[3,39]

Sarcoidosis

Dheeraj Gupta, Om P Sharma

INTRODUCTION

Sarcoidosis, a multisystem disorder, is characterized by depression of cutaneous delayed-type hypersensitivity and a heightened helper T cell type 1 (Th1) immune response in the affected organs. The disease occurs worldwide and affects young and middle-aged adults of both sexes. However, in the past sarcoidosis was considered rare in India and other developing countries. However, in the first decade of the 21st century, sarcoidosis is being recognized frequently because of the increasing awareness and the availability of better diagnostic modalities. In the tropics differential diagnosis from tuberculosis, which is far more prevalent and a close clinical mimic of sarcoidosis, remains a challenge. The lungs are the most frequently involved organs, but its chameleon-like presentation can involve any organ including the eyes, skin, bones, heart, liver and the brain. The diagnosis of sarcoidosis rests on the triad of clinical, radiologic and histologic criteria. Despite extensive research carried out over a century the cause of sarcoidosis remains unknown. The most accepted hypothesis favors an environmental or infectious agent in a genetically susceptible host. The mainstay of treatment is corticosteroids. In general, sarcoidosis has good prognosis.

HISTORY AND EPIDEMIOLOGY

The early descriptions of sarcoidosis were only limited to its skin manifestations. In 1877, Jonathan Hutchinson, a London general practitioner, described a patient with chronic multiple, raised, purplish cutaneous patches over hands and feet. This most likely was the first reported case of sarcoidosis.[1] The term ‘Sarcoidosis’ is credited to Caesar Boeck, who described histological findings of epithelioid cells and giant cells in skin biopsy and termed it “multiple benign sarkoid of the skin,” implying that the histology resembled “sarcoma” but was benign.[2] The major landmarks in the description and understanding of the disease are summarized in Table 96.1. Detailed accounts of history of sarcoidosis have appeared elsewhere.[3,4]

Epidemiology

Sarcoidosis has evolved from a dermatological curiosity in the nineteenth century to a common multisystem disorder in the 21st century. Epidemiology of sarcoidosis has been a confusing field because of the varied clinical presentation of the disease in different parts of the world, despite the fact that there is a vast body of evidence worldwide on the prevalence, racial predilection, familial, geographic, climatic and occupational clustering of sarcoidosis.[16-20] However there are significant differences in disease prevalence between countries, e.g. compared to a high prevalence rate of 28.2/100,000 in Finland; in Japan this is as low as 3.7/100,000 population.[16] The definite prevalence figures are not available from India, but the disease has moved from position of a disease of relative obscurity to an increasing recognition.[17-23] At our hospital, which is a tertiary care referral center for the Northern India, North of Delhi; we have been diagnosing over 100 new cases every year since 2001 (Fig. 96.1).

A Case Control Etiologic Study of Sarcoidosis (ACCESS) conducted across 10 centers in the United

TABLE 96.1: Some important historical landmarks in sarcoidosis

Year(s)	*Landmark*
1869	Hutchinson describes skin lesions
1889	Besnier described “Lupus pernio”[5]
1904	Kreibich described Sarcoid bone cysts[6]
1909	Heerfordt described uveoparotid fever[7]
1916-17	Schaumann recognized multiple-organ involvement and separates sarcoidosis from lymphoma[8]
1939	Association of hypercalcemia or hypercalciuria with sarcoidosis was described[9]
1941	Kveim described a test to help diagnose sarcoidosis[10] Siltzbach later refined and popularized the test[11] James christened the test as Kveim-Siltzbach test.
1946	Löfgren linked erythema nodosum, bilateral hilar lymphadenopathy, fever and polyarthritis[12]
1951	Corticosteroids were first used to treat sarcoidosis[13]
1958	Wurm and colleagues proposed radiographic staging[14] First International Conference held in London, UK
1975	Serum Angiotensin-Converting Enzyme (ACE) was first recognized as a possible biochemical marker by Lieberman[15]
1984	Rizzato started journal Sarcoidosis (now called Sarcoidosis, Vasculitis and Diffuse Lung Diseases)
1987	Rizzato and James formed the World Association for Sarcoidosis and Other Granulomatous Disorders (WASOG)

States, has clarified and confirmed some epidemiological and etiologic aspects of the disease.[24,25] In addition to investigating the possible etiology of the disease, this study examined the psychosocial characteristics[26] and clinical course of 736 patients enrolled in the first six months after histological diagnosis of sarcoidosis and compared them with control subjects paired by age, sex and race. A follow-up study of the first 215 cases was undertaken two years after enrollment.[27] Women were somewhat more likely to be affected, and there were gender differences in clinical manifestations; women tended more to ocular and neurological involvement, whereas men had a higher risk of hypercalcemia. African-Americans were more likely to have uveitis, skin and liver disease. In the United States the lifetime risk of sarcoidosis for those of Afro-Caribbean origin is nearly three times that for Caucasians (2.4 vs 0.85%, respectively).[28]

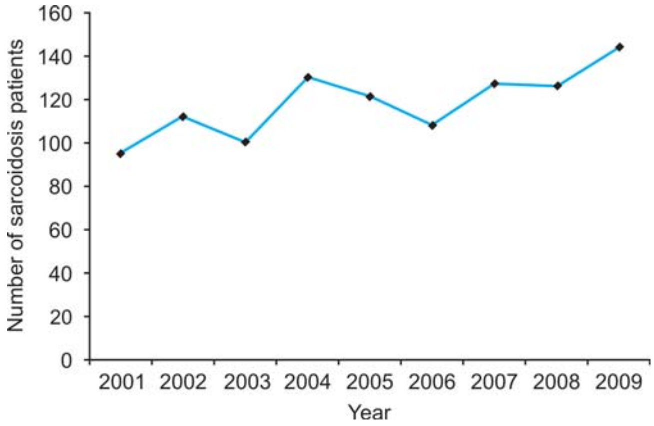

Fig. 96.1: Number of newly diagnosed patients of sarcoidosis from 2001 to 2009 at Department of Pulmonary Medicine, PGI Chandigarh, India

RISK FACTORS

Genetic Predisposition

Clustering of sarcoidosis in families occurs. Nearly 6% of patients in the United Kingdom have an affected relative[29] and the relative risk of sarcoidosis for family members in the United States is 4.7%, siblings have the highest (5.8%) risk.[30] The familial clustering is higher for white than black families. The majority of familial “clusters” involve only parent-child pairs or sibling pairs, more complex pedigrees are rare. This suggests a summation of more than one minor genetic influences rather than a single causative gene mutation.

Blau syndrome, an autosomal dominant chronic granulomatous disease clinically identical to sporadic infantile-onset sarcoidosis, had its gene locus mapped to 16p12-q21 and subsequently both diseases were found to be associated with mutations in the CARD15 gene.[31] However, no association is found with adult sarcoidosis.[32]

In recent years, many of class II MHC alleles have been implicated in the certain aspects of the disease. HLADR5, HLA-DR6, HLA-DR8 and HLA-DR9 seem to confer risk of having disease in Japanese patients, although HLA-DR9 is protective in the Scandinavian population. In German patients, HLA-DR5 is associated with chronic disease and HLA-DR3 with acute forms. Likewise, in Scandinavians, HLA-DR14 and HLA-DR15 are associated with chronic forms and HLA-DR17 with self-limiting ones.[33] The ACCESS study identified a significant association between HLA-DRB1 alleles (specifically HLA-DRB1*1101) and the development of the disease, both in blacks and Caucasians.[24] The only class II allele that was distributed differently among different races with respect to the disease was HLA-DRB1*1501, which was associated with controls in blacks and with cases in whites. This would indicate that, in general, alleles similar to class II HLA may be associated with sarcoidosis in both populations. Similarly, other studies have identified specific alleles of HLA-DQB1 as determining susceptibility to sarcoidosis in the African-American population.[25,34,35] In a study from India presence of DRB1*11 and DRB1*14, and absence of DRB1*07 and DQB1*0201 alleles, were found to be independent predictors of sarcoidosis.[36]

Environmental and Occupational Risk Factors

Barnard et al.[37] based on data from the ACCESS study, observed a greater risk among workers with industrial exposure to organic powders, particularly in those who worked for the suppliers of hardware, building and gardening materials. The jobs associated with childcare and occupational exposure to metal vapors or dusts were not associated with sarcoidosis. These associations were seen particularly among Caucasians.

Occupational exposures identified in the case control studies among Afro-American patients of sarcoidosis were of wood-burning stoves, fireplaces, consumption of water from wells (not from the public mains supply), living or working on a farm,[38] exposed to metals at work, and working in humid places with musty smells.[39]

Tobacco smoking is considered protective for sarcoidosis. In 1961, Comstock et al. in their study of possible risk factors for sarcoidosis observed that patients with sarcoidosis smoked less than matched controls. This inverse association was however noted only among white subjects.[40] Similar findings were subsequently reported in several studies with a reduction in the prevalence of smokers among sarcoidosis patients varying between 21% to 79%.[41-48] The large multicentric ACCESS study demonstrated lesser odds for ever smoking among patients (OR 0.65, CI 0.51-0.82) [49] Fewer alveolar macrophages are recovered by lavage from smokers with sarcoidosis than from normal subjects with a similar smoking history. This supports the possibility that smokers, particularly those with a lower accumulation of alveolar macrophages in the lower respiratory tract, may be less prone to develop sarcoidosis.[41,47] This was further supported by Blanchet and coworkers, who demonstrated in animal models and cell lines that concomitant exposure to nicotine with agents known to induce granulomatous inflammation, had a protective effect.[50] However, simultaneously studies have reported insignificant association or even increased prevalence of smoking among sarcoidosis patients.[51,52] A recent study has reported the impact of active smoking and Environmental Tobacco Smoke (ETS) exposure on disease severity in newly diagnosed cases of sarcoidosis from India. In this study smoking or ETS exposure did not have any significant negative association with sarcoidosis. Also, tobacco smoke did not have any effect on the clinical behavior or disease severity in sarcoidosis.[53]

Infectious Agents as Risk Factors

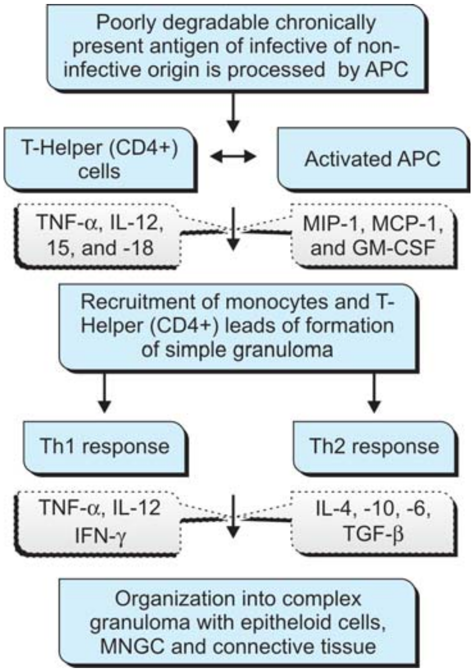
The granulomatous diseases are the result of continued presentation of a poorly degradable antigen.[54] In the case of sarcoidosis, numerous etiologic agents have been incriminated, both infective and noninfective.[55] Non-infective agents have been implicated because of their epidemiologic association,[56] but have not stood the test of time.[57] Examination of the sarcoid granuloma with an electron microscope and immunohistochemical techniques has identified structures similar to organisms such as *Leptospira species, Mycoplasma species* and *Propionibacterium species*.[55] Other microbiological agents that have been implicated from time to time include herpes virus, retrovirus, *Chlamydia pneumoniae*, *Borrelia burgdorferi*, *Rickettsia helvetica*, and finally *Pneumocystis jiroveci*.[55,58] The two strongest contenders are *Propionibacterium* and *Mycobacterium*.[59-61]

From the time sarcoidosis has been described, there has always been a belief that the disease is in some way related to tuberculosis.[62] However, the inability to identify mycobacteria by histologic staining or culture from pathologic tissues continues to be one of the strongest arguments against a potential role for mycobacteria. A recent meta-analysis suggested a 30% prevalence rate of mycobacterial DNA in sarcoid samples but the individual studies reported detection rates from 0% to 50%.[63] Moreover, most of these studies were published from countries with low prevalence for tuberculosis. If indeed mycobacteria are etiologically linked to sarcoidosis then the detection rates for mycobacterial Deoxyribonucleic Acid (DNA) in sarcoid samples would be higher in countries with high prevalence of Tuberculosis (TB). A recent prospective case-control study aimed at the detection of mycobacterial DNA in patients with sarcoidosis from India, has reinforced the hypothesis by showing mycobacterial DNA with PCR for 65 kDa protein gene in 48% of samples [Bronchoalveolar Lavage (BAL) or biopsy] from freshly diagnosed patients of sarcoidosis.[64]

The factors that favor mycobacteria being a trigger for sarcoidosis include histopathological appearances of the granulomas,[54] reports of mycobacterial disease either existing before, during or after sarcoidosis[65,66] and the finding of mycobacteria in occasional granulomas of sarcoidosis.[67-69] Passage experiments have also suggested that mycobacteria with the characteristics of *Mycobacterium tuberculosis* may be the incriminating agent.[70-73] Recent studies on humoral immunity to mycobacterial antigens from sarcoidosis patients have renewed interest in a potential of mycobacteria in sarcoidosis.[74] It has been shown that mycobacterial ESAT-6 and katG are recognized by sarcoidosis CD4+ T cells when presented by known sarcoidosis susceptibility allele, DRB1*1101.[75] It is possible that the presence of mycobacterial infection or BCG vaccination in genetically predisposed host may be involved in the development of autoimmunity.[76] It has also been suggested that the organism might exist in a cell wall deficient L-form and may be difficult to isolate.[77] Evidence even if tantalizing, is not conclusive to support the contention that tubercle bacillus causes sarcoidosis.

PATHOGENESIS AND IMMUNOLOGY

Non-caseating granuloma is the hallmark of sarcoidosis. The granulomatous reaction is a protective response to an inciting agent. It limits inflammation and protects the tissue. Though exact antigen inciting this response is yet unclear and it may in fact be different in different patients and different demographic areas (Fig. 96.2). Essentially there are four stages involved. First is the presence of the inciting antigen and its contact with Antigen Processing Cells (APC), which are mostly the alveolar macrophages. Second stage is the interaction APCs and CD4+ T lymphocytes to initiate the formation of a simple granuloma, Third stage includes further recruitment of CD4+ T-lymphocytes and elicitation of Type 1 and Type 2 helper responses, which lead to the final or fourth stage of formation and maintenance of complex granulomas. Macrophages differentiate to form epithelioid cells under the influence of cytokine production. These epithelioid cells fuse to form Multinucleated Giant Cells (MNGC) and gain secretary properties. Granulomas secrete many chemicals, including calcitriol and angiotensin converting enzyme. These events, however, are dependent on a susceptible genetic background described by a variety of functional polymorphisms.[78,79]



Poorly degradable chronically present antigen of infective of non-infective origin is processed by APC
T-Helper (CD4+) cells
Activated APC
TNF-α, IL-12, 15, and -18

Fig. 96.2: Hypothesis of the development of granulomatous inflammation in sarcoidosis

What Controls the Course of Granulomas?

Extensive research over past two decades has helped to delineate the sequence of events in the immunopathogenesis of sarcoidosis. The earliest event is accumulation CD4+ helper T cells and release of Interleukin-2 (IL-2) in the alveoli and interstitium.[80-82] This is followed by a progressive and selective oligoclonal expansion of αβ T cell.[83] There is increased in situ production of Th1 cell-derived cytokines (IL-2 and IFN-γ) during granuloma formation.[84,85] The alveolar macrophages in sarcoidosis have immense secretary properties and there is an increased release of macrophage-derived cytokines (IL-1, IL-6, IL-8, IL-15, TNF-α, IFN-γ, GM-CSF) and chemokines (RANTES, MIP-1α, IL-16). Most of these cytokines favor granuloma formation and lung damage.[86-89] The progression and maintenance of granulomatous reaction is also helped by the accumulation of these monocyte-macrophages with antigen-presenting cell capacity and expressing the increased levels of activation markers (HLA-DR, HLA-DQ, CD71) and adhesion molecules (CD49a, CD54, CD102). The chemoattractant cytokines like IL-8, IL-15, IL-16 and RANTES recruit the CD4+ T cells from the peripheral blood to the site of inflammation,[85-87] while IL-2 induces an *in situ* proliferation of these cells.[90,91] The mechanism(s) that result in spontaneous resolution or progression to chronic disease and fibrosis are unclear but may be linked to host susceptibility and genetic factors. The sarcoid granulomatous inflammation is characterized by an altered balance of Th1/Th2 responses with a dominant expression of Th1 cytokines [IFN-γ and interleukin (IL)-2] with the low levels of expression of T helper 2 (Th2) cytokines (IL-4 and IL-5).[82,92] IL-12 contributes to proliferation of activated T cells in early disease. Elevated levels of IL-6 and IL-8 are reported in the BAL fluid of active sarcoidosis, and these may modify the disease process. IL-15 may aid in the proliferation of T and B cells.[93] IL-12 and IL-18 are also increased in the lungs of sarcoidosis, and they stimulate IFN-γ production.[82,94] Transforming Growth Factor-Beta (TGF-β) is an inhibitor of IL-12 and IFN-production. Its production is increased in those patients undergoing the remission of sarcoidosis, suggesting a key role for TGF-β in the down regulation of granulomatous inflammation of sarcoidosis.[95]

Another clinically important phenomenon that occurs in sarcoidosis is the depression of delayed type hypersensitivity. Commonly utilized as a diagnostic tool, this is often impaired in active sarcoidosis and not seen when sarcoidosis resolves. A subgroup of CD4+ T cells may account for this anergy by abolishing IL-2 production and inhibiting T cell proliferation.[96,97] It is also suggested that anergy state may be related to diminished dendritic cell function.[98]

PATHOLOGY

The most common organs of involvement are lymph nodes, lungs, liver, spleen and skin. In lungs the common site of involvement is along the bronchovascular spaces (lymphangitic pattern), that makes the transbronchial biopsy a preferred choice for obtaining histological diagnosis. However, any organ can be involved and the histological features are similar in all organs.[13,99,100] Many a times, the pathological involvement of organs may remain clinically silent, making sarcoidosis an iceberg syndrome (Fig. 96.3). Pulmonary vascular involvement has also been reported quite frequently.[101]

Sarcoidosis: An Iceberg Syndrome

Fig. 96.3: Sarcoidosis: An Iceberg syndrome. Pathological involvement of various organs may not be clinically apparent

The hallmark of sarcoidosis is the noncaseating, compact, "naked" granulomas. On histology, a sarcoid granuloma is comprised of lymphocytes, macrophages, well differentiated epithelioid cells, multinucleated giant cells, fibroblasts and mast cells. The sarcoid granulomas have CD4+ T cells in the center and CD8+ T cells and B lymphocytes in the periphery.[13,102-104] Histologic findings differ based on the stage of the disease. In early stages of disease, the sarcoid granuloma is a compact structure that consists of radially arranged pale, pink epithelioid cells seen most often in the center of the granulomas. Lymphocytes and fibroblasts form a surrounding rim. Multinucleated Langerhans' type giant cells, usually only a few, are often seen in the granuloma. Caseation is absent. However, focal coagulative necrosis may be seen.[103] In rare cases, fibrinoid necrosis is seen in nodular and necrotizing sarcoid granulomatosis.[105,106] Nonspecific cytoplasmic inclusions can be seen in sarcoidosis, such as asteroid bodies, Schaumann's bodies, Hamazaki-Wesenberg bodies and calcium oxalate crystals. Granuloma may resolve totally with or without therapy. It may also persist and show hyalinization. In chronic sarcoidosis, fibrosis and scarring occur.[103,105]

CLINICAL FEATURES

In spite of the common observations that sarcoidosis often presents with significant clinical and radiological features, and that clinical medicine is relied upon rather heavily in most developing countries, the physicians in India are generally reluctant to make the diagnosis of sarcoidosis. The physician's reluctance is partly attributed to the belief that it is rarer in India and more importantly to the overwhelming prevalence of tuberculosis, which presents with very similar clinical, radiological and histological findings.

Besides thoracic manifestations, both sarcoidosis and tuberculosis involve multiple organs. Although the involvement of extrapulmonary sites was considered less frequent, a systematic review and cumulative analysis of all the major studies from India that have reported on clinical features (Table 96.2) show almost similar figures as reported from other countries, while extrapulmonary lymphadenopathy is distinctly more frequent.[107] Lung is the most common organ affected with sarcoidosis, the

disease may involve any part of the body.[27] Prominent manifestations of sarcoidosis are described below, and the similarities and differences from tuberculosis have been discussed subsequently.

Pulmonary Involvement

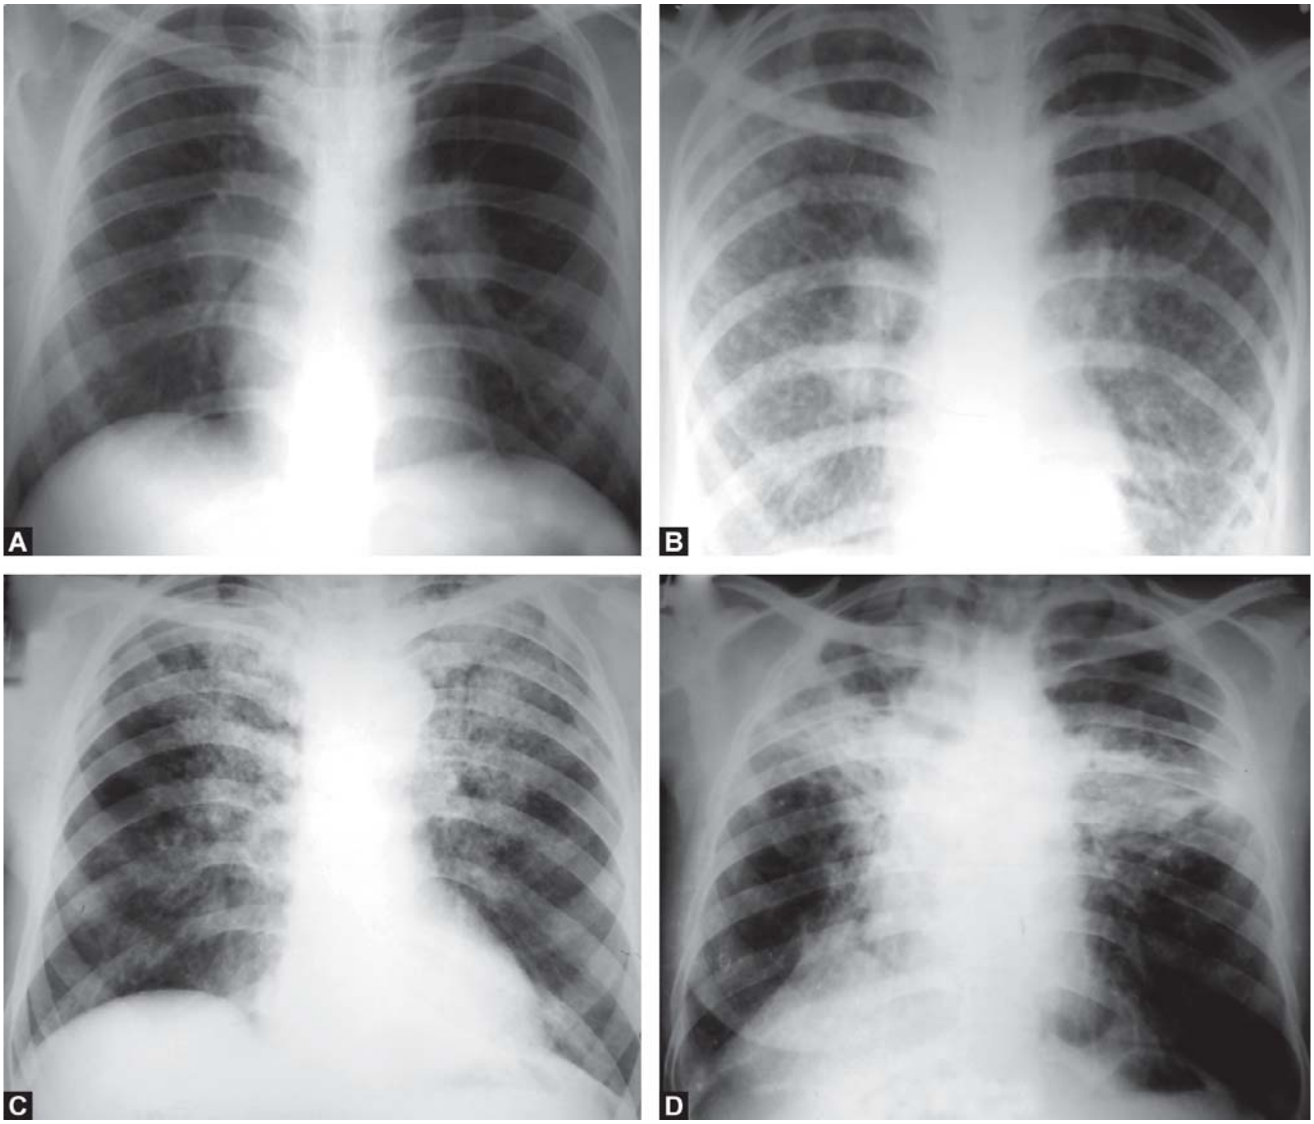
Clinical

The symptoms of sarcoidosis are often nonspecific and 20% to 50% of patients with sarcoidosis are asymptomatic. The diagnosis is pursued after an abnormality is detected on a chest X-ray film obtained for an unrelated reason.[118] Dry cough and dyspnea are the most common clinical symptoms attributable to the intrathoracic manifestations of sarcoidosis. Chest pain may be present and is often vague and nonspecific; however, it may be severe and suggestive of cardiac pain.[119,120] Chest pain may also indicate an unusual complication such as pleuritis or pneumothorax, or possibly pulmonary embolism, as antiphospholipid antibody syndrome has been associated with sarcoidosis on rare occasions.[118] Wheezing suggests airway obstruction secondary to endobronchial granulomatous disease, extrinsic compression by mediastinal adenopathy, or bronchial distortion secondary to fibrotic lung disease. Wheezing may also be contributed by bronchial hyper-reactivity.[121,122] A productive cough may indicate traction bronchiectasis due to parenchymal fibrosis, hemoptysis suggests bronchiectasis or the presence of an aspergilloma.

Radiographic Findings

The chest radiograph is abnormal in more than 90% of sarcoidosis patients and diagnosis of sarcoidosis is first suspected on routine chest roentgenography in most patients. Bilateral hilar lymphadenopathy is noted in 50% to 85% of cases. The presence of symmetrical bihilar and mediastinal lymphadenopathy is almost characteristic in sarcoidosis. Lymph nodes are generally big and sharply defined, with a clear line of translucency between the mediastinal shadow and the nodes—classically described as “potato nodes.” Unilateral hilar adenopathy is rare and pulmonary parenchymal infiltrates are seen in 25% to 60% of patients. Typically the infiltrates are bilateral and symmetrical and are most common in the upper and mid lung fields.[123,124]

A chest radiographic staging system[125] for sarcoidosis is shown in Table 96.3 and Figs 96.4A to D.



Figs 96.4A to D: Typical chest radiographs in sarcoidosis. Panel A: Stage 1, showing bilateral hilar and paratracheal lymphadenopathy; Panel B: Stage 2, Hilar and paratracheal lymphadenopathy with pulmonary infiltrates; Panel C: Stage 3, Pulmonary infiltrates with no lymphadenopathy; Panel D: Stage 4, Pulmonary fibrosis with architectural distortion

Higher radiographic stages have been associated with poorer prognosis.[126,127] However, there is significant overlap between the groups and prognosticating individual patients based on radiographic stage alone are unreliable. Nevertheless, the patients with stage IV chest radiographs rarely undergo spontaneous remission. In Stage IV pulmonary sarcoidosis the lung parenchyma is destroyed with upward traction of the hila, lung distortion, upper lobe volume loss, fibrocystic disease, honeycombed cysts and reduced lung volumes. Large bullae may house one or more fungus balls or an

TABLE 96.3: Chest radiographic staging of sarcoidosis

Stages	*Features*
Stage 0	No involvement
Stage 1	Bilateral hilar adenopathy, often with right paratracheal adenopathy
Stage 2	Stage 1 + Pulmonary infiltrates
Stage 3	Pulmonary infiltrates without adenopathy as described in stage 1
Stage 4	Advanced parenchymal lung disease, including fibrosis, honeycomb lung, traction bronchiectasis, cysts, bullae, and emphysema, with or without adenopathy

aspergilloma (Figs 96.5A and B).[128] Cystic or traction bronchiectasis may develop.

Chest computed tomography (CT) though reveals more disease than the chest radiograph, there is no evidence that CT has a superior prognostic or therapeutic value compared with the chest radiograph in the management of pulmonary sarcoidosis. Currently chest CT is not a recommended standard test for sarcoidosis.[3] Computed tomography scans can have several typical and atypical findings.[123,129] Typically the high-resolution CT reveals nodules along the bronchovascular bundle and subpleural regions.[129,130] Coalescence of these granulomata may result in mass-like lesions with or without air bronchograms. Occasionally these conglomerate nodules are surrounded by small nodules giving an appearance that is known as “sarcoid galaxy sign” (Figs 96.6A to D).[131] More extensive lymphadenopathy is also more commonly seen on CT than the typical hilar and paratracheal nodes seen on chest radiograph. Ground glass attenuation, often thought to represent acute alveolitis, has been shown to represent granulomatous inflammation.[132] “Reverse halo” sign typically described with invasive fungal infections has also been reported in sarcoidosis recently.[133] Typical findings, if found may be useful in suggesting sarcoidosis in the evaluation of an undiagnosed interstitial lung disease.

Functional Abnormalities

Pulmonary function abnormalities can be seen in 20% to 40% sarcoidosis patients with a normal lung parenchyma on a chest radiograph and 50% to 70% of cases when the lung parenchyma is visibly abnormal.[134] These include abnormalities in the vital capacity, diffusing capacity, PaO_2 at rest, PaO_2 with exercise and lung compliance.[134] Lung function testing with the help of spirometry is a simple procedure to grade the disease extent. Lung function changes have been shown to bear a clinical correlation with overall histopathological scoring assessed from the granuloma load and interstitial inflammation.[113,135] Lung functions have also been correlated with the radiological extent of the parenchymal disease; patients with stage IV fibrocystic disease have the most severe pulmonary function impairment.[136] Being an interstitial lung disease, a restrictive ventilatory defect is to be expected. However, as mentioned previously, endobronchial involvement may result in airflow obstruction being the major abnormality on pulmonary function testing. In addition, airflow obstruction is common in chronic sarcoidosis, possibly the result of airway distortion from lung fibrosis. Granulomatous involvement of skeletal muscle occurs in 50% to 80% of patients with sarcoidosis and this may affect respiratory muscle function in sarcoidosis.[137] Measurements of respiratory pressures has been used as an index of functional work capacity and reflection of activities of daily living.[138] Pulmonary hypertension is a serious complication of pulmonary sarcoidosis and is a risk factor for death.[139] Pulmonary hypertension may occur via a number of mechanisms, including parenchymal fibrosis distorting the pulmonary vasculature (pulmonary arterial or venous system), granulomatous inflammation of the pulmonary vasculature, hypoxic pulmonary arterial vasoconstriction from parenchymal

pulmonary disease, and from elevated left ventricular end diastolic pressure because of cardiac involvement with sarcoidosis.[139,140]

Other Intrathoracic Manifestations

Pleural involvement (including effusions and thickening) may be detected in 5% to 10% of patients with sarcoidosis (Fig. 96.7). Pleural effusions are estimated to occur in 1 to 3% of patients with sarcoidosis and are more likely to be seen in patients with stage 2 and 3 disease.[141,142] These effusions are more often right-sided (45% vs 33% left- sided and 22% bilateral), have relatively few cells (mostly lymphocytes), and are often discordant with respect to Light's criteria in that the effusions are characteristically exudative by protein criteria and transudative by Lactate Dehydrogenase (LDH) criteria.[141] Chylothorax, hemothorax and pneumothorax have also been reported rarely.[143-145] Contrary to the infrequency with which the above pleural diseases affect patients with sarcoidosis, pleural thickening on CT scan may be seen in up to the one-third of patients, the clinical significance of which remains unclear.[146]

Hemoptysis, at times serious, can occur due to a variety of reasons such as formation of a fungal ball (Aspergilloma) in a pre-existing cyst or cavity, bronchiectasis (most often due to traction in association with parenchymal fibrosis) and necrotizing sarcoid angiitis.[147,148] Rare consequences of mediastinal lymphadenopathy include superior vena cava syndrome,[149] mediastinal lymph node calcification and mediastinal fibrosis.[150] Rarely giant bullae resulting from sarcoidosis may lead to the "vanishing lung syndrome."[151] Several of these rare manifestations have also been documented from India.[152]

Extrapulmonary Involvement

Involvement of extrapulmonary sites is fairly common and often of major clinical importance. When carefully looked for, one or more of the extrapulmonary organs were involved in about two-thirds of patients from

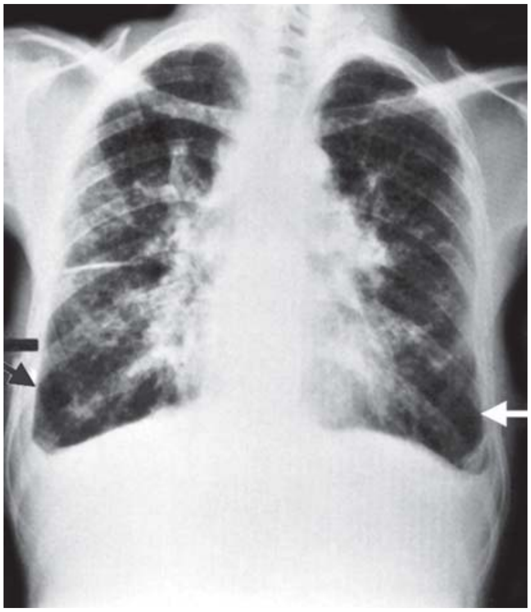

Fig. 96.7: Bilateral pleural thickening in sarcoidosis

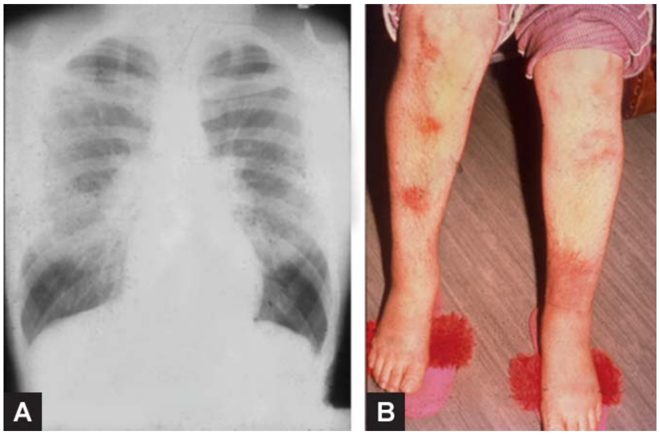
Chandigarh, India.[21] Constitutional symptoms of fever, night sweats, weight loss, fatigue, myalgia and arthralgia occur very frequently with extrathoracic sarcoidosis. Fatigue, in particular, is an important symptom.[153] Although any organ can be involved, skin and eyes are most common, whereas cardiac and neurological involvements are most serious. Major extrapulmonary manifestations of sarcoidosis are outlined below, detailed descriptions can be found elsewhere.[154,155]

Skin

Erythema nodosum (EN), subcutaneous nodules and plaques, lupus pernio and maculopapular eruptions are the important manifestations of sarcoidosis.[156] Skin lesions are divided into two categories: Specific and nonspecific. Specific lesions demonstrate granulomatous inflammation on biopsy. Nonspecific skin lesions are inflammatory skin reactions with no evidence of granulomatous inflammation. Erythema nodosum is the most common nonspecific skin lesion of sarcoidosis. It presents as tender nodules on the extremities. Erythema nodosum with hilar lymphadenopathy (Löfgren's syndrome, also often with polyarthropathy and nongranulomatous uveitis) is a typical subset of sarcoidosis with particular characteristics (Figs 96.8A and B). Known to carry a very favorable prognosis for resolution, it has been described with a spring seasonal peak in both the Northern and Southern Hemispheres.[141,142] Specific skin lesions are usually asymptomatic. Disfigurement is the most common complaint. The most common lesions are firm, 2 to 5 mm papules that often have a translucent red-brown or yellow-brown appearance. Lupus pernio is the most severe form of dermatological manifestation that usually affects the nose, cheeks, lips and ears in the form of indolent, red-purple or violaceous skin lesions. These lesions can erode into cartilage and bone, especially around the nose.[157-159] Lupus pernio is associated with the poor prognosis of sarcoidosis and is associated with more severe pulmonary disease.[160,161]



Figs 96.8A and B: Löfgren syndrome: bilateral hilar adenopathy + erythema nodosum

Eye

Eyes are involved in sarcoidosis in up to 25% patients and it can affect any part of the eye and may be the major manifestation of the disease.[162,163] Japanese patients have ocular involvement in more than 70% patients.[164] A careful eye check-up should be a part of routine clinical workup of sarcoidosis. Uveitis is the most common ocular manifestation of sarcoidosis.[165] Depending upon the site of involvement the symptoms vary from blurred vision, red eye, painful eye or photophobia in anterior uveitis to vision loss in posterior uveitis. Retinal perivasculitis, retinal scarring and glaucoma can also occur. One-third of the patients with anterior uveitis have no symptoms (a "quiet eye").[163,166] Besides uveitis, involvement of lachrymal glands is also common, which may occasionally cause dry eyes. Optic neuropathy is rare, but can result in rapid, permanent vision loss.[163,166,167] Funduscopic exam shows papillitis, papilledema and neovascularization with optic atrophy ultimately. This condition is an ophthalmologic emergency and mandates immediate systemic therapy.

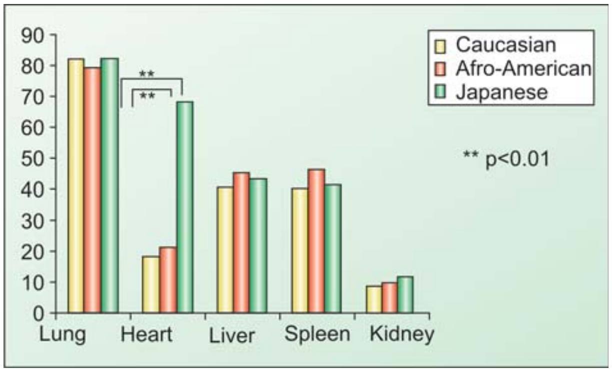


Fig. 96.9: Frequency of organ involvement in sarcoidosis. Cardiac involvement is much higher in Japanese patients than other groups

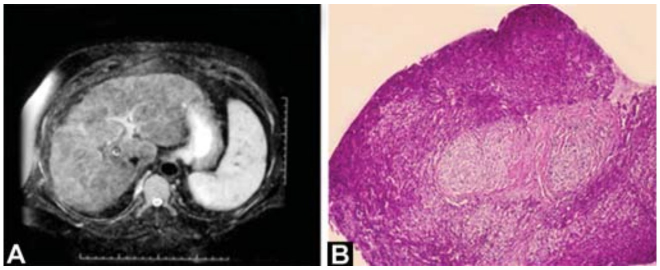
Cardiac and Neurologic

Rare cardiac or neurologic sarcoidosis are important to recognize as they may be life-threatening. Though clinically detectable in only 5% of sarcoidosis patients, cardiac involvement may be picked up in 25% patients at autopsy.[168,169] Japanese show a markedly higher rate of cardiac involvement compared to the Caucasians and Afro-Americans (Fig. 96.9). Cardiac sarcoidosis may cause left ventricular dysfunction and cardiac arrhythmias that can result in sudden death.[170-173] Endomyocardial biopsy is the gold standard diagnostic test, which is very specific, however it has a poor sensitivity of less than 25% because of sampling error.[174] For the noninvasive diagnosis of cardiac involvement in sarcoidosis various investigations such as echocardiography, thallium scanning, gallium scanning, Magnetic Resonance Imaging (MRI) or Positron Emission Tomography (PET) scanning can be used coupled with a typical clinical presentation.[173, 175-181]

Sarcoidosis can mimic diverse neurological conditions. Diagnosis of neurosarcoidosis is based on a confirmation of systemic sarcoidosis since pathologic confirmation is rarely available from the Central Nervous System (CNS). Central nervous system infection and malignancy should be reasonably excluded before making a diagnosis of CNS sarcoidosis.[182] Overall CNS involvement may be seen in about 10% patients of sarcoidosis.[183] The most common manifestation of neurosarcoidosis is seventh cranial nerve palsy, and it may precede the diagnosis of the disease. Sarcoidosis may affect any part of the nervous system causing a cranial nerve palsy, mononeuropathy or polyneuropathy, aseptic meningitis, seizures, mass lesions in the brain or spinal cord, and encephalopathy.[184,185] Rarely it may also mimic multiple sclerosis.[186]

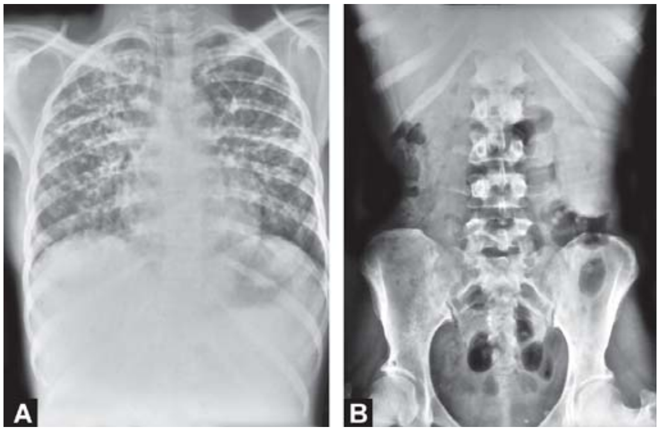


Figs 96.10A and B: Hepatic sarcoidosis

Other Extrapulmonary Organ Involvement

Sarcoidosis may affect gastrointestinal, Ear, Nose and Throat (ENT), hematological, endocrinal, genitourinary and musculoskeletal systems.[187] Almost all types of organs involvement have been described from India and the other developing countries as well. Asymptomatic histological involvement of liver may be seen in 50% to 65% patients. Abnormalities in liver function tests are seen in less than 35%, the most common abnormality being an elevation in the serum alkaline phosphatase (Figs 96.10A and B).[188-192] Similarly spleen may also be involved with minimal or no symptoms. Large splenomegaly with hypersplenism is seen more commonly in Afro-American patients (Figs 96.11A and B).[193-196] Sarcoidosis causes clinically apparent peripheral lymphadenopathy in more than 10% of patients.[197] Sarcoidosis of the upper respiratory tract is underappreciated. It may occur in the nasopharynx, hypopharynx, larynx, sinuses or rarely vocal cord palsy.[198,199]

Typical bone lesions of sarcoidosis are small cysts or cortical defects in the small bones of the hands or feet, which occur occasionally (about 4% in one series) and



Figs 96.11A and B: A patient with sarcoidosis and massive splenomegaly. Enlarged spleen and hypersplenism is common in African-American patients

are possibly more frequent in females and in patients with lupus pernio.[200] Joints if involved acutely, as is often seen in patients with Löfgren's syndrome carry a good prognosis.[201] Chronic sarcoid arthritis is rare but can progress to cause joint deformities.[202,203]

Abnormalities of Calcium Metabolism

On any general medical ward, there are three common causes of hypercalcemia: hyperparathyroidism, lymphoma or malignancy, and sarcoidosis. In sarcoidosis hypercalcemia has been reported to occur in 2% to 63% of patients; hypercalciuria is three times more common than hypercalcemia.[204] Therefore serum and urine calcium levels should be measured regularly over the whole course of the illness. The mechanism of hypercalcemia in sarcoidosis is due to excess extrarenal calcitriol production.[205] The alveolar macrophages present within the granulomas contain the enzyme 1-α hydroxylase, which converts precursor vitamin D to active calcitriol.[206] Normally high levels of calcitriol cause feedback inhibition of 1-α hydroxylase; calcitriol also causes up regulation of 25 (OH)D3 24 hydroxylase, the enzyme which converts 25 (OH)D3 to 24, 25 (OH)2D3, the metabolically inactive form of vitamin D. Both the feedback mechanisms are lost in alveolar macrophages which lead to the continuous production of calcitriol.[207] Another recently described mechanism is the excess production of parathyroid hormone related peptide (PTHrP), which like parathyroid hormone causes upregulation of 1-α hydroxylase.[208] Unlike parathyroid hormone, PTHrp is not regulated by calcium but by interleukin-2 and tumor necrosis factor α both of which are increased in sarcoidosis.[209] It is possible that these cytokines released by the alveolar macrophages act in a paracrine fashion to up regulate PTHrP production by the macrophages.[207] Hypercalciuria or hypercalcemia can lead to nephrolithiasis and renal failure. Rarely hypercalcemia may cause acute pancreatitis.[210]

DIAGNOSIS

The diagnosis of sarcoidosis rests on a triad of clinical, radiologic and histological criteria. If the clinical and radiologic picture is typical and tuberculosis is definitely excluded then sarcoidosis can be presumptuously diagnosed. However, in the absence of positive biopsy diagnosis of sarcoidosis will remain in doubt. Most often, the chest radiograph showing hilar and mediastinal lymphadenopathy raises the suspicion of sarcoidosis. But, there are many causes of hilar and mediastinal lymphadenopathy (Table 96.4). Diagnosis in the presence of atypical radiological findings or Interstitial Lung Disease (ILD) is more difficult. While the presence of hilar adenopathy in a patient with ILD is a clue to the diagnosis of sarcoidosis (stage II), it is difficult in the presence of only the interstitial infiltrates (stage III) or pulmonary fibrosis (stage IV). High Resolution CT (HRCT) scan is helpful to delineate interstitial involvement, but the etiological diagnosis often needs histological investigations. The algorithm meant for diagnosis of ILD in the developing countries can be followed in all such patients.[211]

- Granulomatous lesions of unknown significance (GLUS syndrome)

Adapted from reference 3; Conditions marked with (*) can also present with hilar and mediastinal lymphadenopathy.

Histological Diagnosis

Biopsy is indicated for all patients presumed to have sarcoidosis, except those with Löfgren's syndrome.

Because of the varied clinical presentations of sarcoidosis, one should select the least invasive biopsy site.[212] Although the biopsy of peripheral lymph nodes or other organs had been practiced since long, the outcome had never been universally useful. This was because the other organs are not involved as frequently as the lungs. Moreover some of the internal organs are difficult to approach and take biopsy from. A lung biopsy obtained with the help of fiberoptic bronchoscopy has made a major difference in the diagnosis of sarcoidosis in India.[213] Transbronchial lung biopsy is positive in over 80% of patients of sarcoidosis.[17, 214, 215] Similar diagnostic yield is obtained in almost all stages of sarcoidosis.

Combining endobronchial with transbronchial biopsy improves the diagnostic yield by about 10%.[216,217] Endobronchial abnormalities are more commonly seen in patients with respiratory symptoms.[217] Labial biopsy has also been shown to have a high discriminatory value in the differentiation of sarcoidosis from tuberculosis.[218] Mediastinal lymph node biopsy is often confirmatory.[219] Transbronchial Needle Aspiration (TBNA), a widely used procedure, has a diagnostic sensitivity of almost 100%.[220-222] Combiming TBNA with Endobronchial Ultrasound (EBUS) increases the sensitivity with or without onsite cytologists.[223-229]

The characteristic findings on biopsy is the presence of compact noncaseating epithelioid cell granulomas, however, an alternative diagnosis has to be excluded. A general differential diagnosis of granulomatous inflammation is given in Table 96.4.

Tuberculin Skin Test (TST)

The tuberculin sensitivity is depressed in sarcoidosis even in the background of high prevalence of tuberculosis and a cut-off of 10 mm reaction to 5TU tuberculin test has virtually 100% sensitivity for sarcoidosis, however, it is not specific.[112] The problem is further confounded by the coexistence of two diseases.[230] A negative tuberculin test is heavily relied upon for diagnosis of sarcoidosis. It is cheap and simple to perform. A positive TST in a patient suspected to suffer from sarcoidosis should alert the treating physician for a thorough work-up for tuberculosis.

Miscellaneous Investigations

Bronchoalveolar lavage: Bronchoalveolar lavage has also been frequently used. Studies have shown a very high positive predictive value for the diagnosis of sarcoidosis with an elevated ratio of CD4/CD8 in BAL fluid. However, the samples require >15% lymphocytes on cell count to be useful.[231] A CD4:CD8 ratio greater than 3.5 shows a high specificity of 93% to 96% for sarcoidosis, but the sensitivity is low (53% to 59%).[232]

Kveim test: The Kveim–Siltzbach test is performed using intradermal injections of human sarcoid tissue. Four weeks later the papule that forms at the site of the injection is biopsied. Kveim's test had been reported as a reliable test for the diagnosis of sarcoidosis with positivity of even up to 98%.[11,233] But a validated good quality antigen is not available.[234] Moreover, it requires four to six weeks following intradermal injection of the antigen before a positive reaction is obtained. This generally is a long period to wait, especially in symptomatic or hospitalized patients. Further, the frequency of positivity depends upon the disease-duration. There is also a risk of transmission of the etiological agent by the Kveim test. Mechanism of the Kveim test vis a vis sarcoidosis is still not clearly understood.[235] Its clinical application is limited.

Serum angiotensin converting enzyme (SACE): SACE estimation was introduced as a promising test of diagnosis in the mid-seventies.[15] A rise in SACE activity in active sarcoidosis has been shown in a few reports from this country as well.[236,237] Angiotensin converting enzyme is produced by the epithelioid cells of sarcoid granulomas. As other disorders such as diabetes mellitus, cirrhosis, acute hepatitis, chronic renal disease, silicosis, Gaucher's disease, leprosy, asbestosis and berylliosis may demonstrate elevated SACE levels, the test is neither sensitive nor specific enough to be used as a diagnostic tool.[223,224] Overall clinical sensitivity for elevated SACE levels is about 55% with a specificity of 90%.[225] There is also no apparent association between serum ACE level and radiographic staging.[223] In spite of the lack of specificity as a test for sarcoidosis, SACE provides a good monitor of disease activity. The presence of inhibitors may interfere with SACE levels unless sensitive radioimmunoassay techniques are used for assessment.[226] Some studies have suggested that SACE levels may vary with genetic factors and the use of genotype corrected ACE levels may make it a more useful diagnostic tool.[227,228]

Other tests: Gallium scanning demonstrates inflammation throughout the body. Its use has largely fallen out of favor due to the advances in bronchoscopic techniques. Uptake in the hilar lymph nodes and right paratracheal nodes results in the "lambda sign," whereas lacrimal and salivary gland uptake results in the "panda sign."[229] Fluorodeoxyglucose-positron emission tomography (FDG-PET) scanning is emerging as a potentially useful study in the diagnosis of sarcoidosis.[238] Fluorodeoxyglucose uptake is found in up to two-thirds of patients with stage 2 and 3 disease, whereas negative uptake is associated with stage 0, 1 and 4 disease. In addition, FDG-PET has been demonstrated to assist in detecting clinically silent sites, which may be biopsied for definitive diagnosis. F-methyltyrosine-PET (FMT-PET) uses an amino acid that is preferentially taken up and expressed on the surface of tumor cells, and is negative in patients with sarcoidosis.[239]

Assessment of Activity

Assessing activity and/or severity of disease is sarcoidosis is a tough task as no single variable in isolation is accurate.[240] Several laboratory and cell biological markers in serum [e.g. ACE, lysozyme, neopterin, soluble IL-2-receptor, Soluble Intracellular Adhesion Molecule (ICAM)-1, IFN-γ] or in BAL fluid (e.g. high lymphocytes, activation marker expression on T-cells, CD4/C8 ratio, macrophage Tumor Necrosis Factor-Alpha (TNF-α) release, collagenase, procollagen-III-peptide, vitronectin, fibronectin, hyaluronan) have been studied as potential indices of active disease. [241-243] However, nothing can be recommended for routine assessment, perhaps with the exception of serum ACE.[244] The magnitude of the initial ACE levels has no prognostic significance and the initial levels are no different between patients who deteriorate and those who improve. After the initiation of treatment, serum ACE levels can be helpful in monitoring the treatment effect, since increased serum ACE activity will usually be reduced within a few weeks of the start of corticosteroid treatment. At present, still the best way to assess the activity of sarcoidosis is through clinical activity. This is based on the mode of onset, the worsening or persistence of symptoms, and the presence of skin lesions, in combination with changes in chest radiography and lung function tests, with or without treatment. Pulmonary function studies have shown rough correlation with histological severity and may be used as a surrogate.[115]

THE TUBERCULOSIS ENIGMA

Relationship between sarcoidosis and tuberculosis remains a riddle. Caesar Boeck, a Norwegian dermatologist, who probably first time described the histological appearance of sarcoidosis as "multiple benign sarcoid of the skin," believed that the histological features resembled sarcoma. Nevertheless, the remarkable similarity of sarcoidosis to tuberculosis in both the clinical and histological features was soon noticed. A possible link between the two conditions has been debated ever since.[62] The possible relationship has implications in three areas: i. pathogenesis, ii. diagnosis and iii. treatment.

Almost a quarter of a century ago, in a cooperative study of sarcoidosis in several countries of Asia, the authors commented that the chronological increase in sarcoidosis was related to the decrease in infectious diseases represented by tuberculosis.[245] This evidence on tuberculosis relationship of sarcoidosis is weak and needs to be reanalyzed. Sarcoidosis has increased in India; this has happened in spite of the continued high prevalence of tuberculosis.

Sarcoidosis and tuberculosis mimic each other not only in clinicoradiological presentations, but also in the results of several investigations, including histopathology. In such situations the differential diagnosis may become impossible, particularly when the two diseases can rarely coexist.[230] Hilar lymphadenopathy, the commonest clinical presentation of sarcoidosis is also a manifestation of tuberculosis.[246] However, the nodes in sarcoidosis only rarely show a central hypodensity on CT scan, which is frequently observed finding in tuberculosis.[129] Fibrosis, especially in the apical regions, can occur in both conditions although cavitation is rarer in sarcoidosis.[247] Similarly, miliary distribution of lesions, characteristically described in tuberculosis, can also occur in sarcoidosis.[248, 249] Miliary disease in particular poses a great difficulty in differential diagnosis particularly in India where it is considered a sine qua non for tuberculosis.[250] In fact, most patients of miliary sarcoidosis, described from India, had received antitubercular therapy before the diagnosis of sarcoidosis was established.[248,249] A report from Greece describes a patient of miliary sarcoidosis one year after successful treatment for miliary tuberculosis.[251]

The tuberculin sensitivity is depressed in sarcoidosis even in the background of high prevalence of tuberculosis and a cut-off of 10 mm reaction to 5TU tuberculin test has virtually 100% sensitivity for sarcoidosis.[110] A negative tuberculin test excludes tuberculosis except in seriously sick or otherwise immunosuppressed individuals. Diagnosis of tuberculosis in tuberculin negative individuals is required to be supported by strong bacteriological evidence.[252] A positive tuberculin test in sarcoidosis should also be looked with high suspicion as discussed above. In India, tuberculin test is positive in about 30% to 50% of general population and in 64% to 85% in the age group of 25–45 years.[253,254] A higher cut-off point of tuberculin test is therefore suggested to diagnose tuberculosis.[255]

Interferon-Gamma Release Assays (IGRAs) have a higher sensitivity and specificity for detecting Mycobacterium Tuberculosis (MTB) infection than the conventional TST, as they utilize antigens specific for MTB complex.[256] Clinicians in high prevalence countries erroneously make a diagnosis of tuberculosis based on a positive IGRA test. In clinical practice we have observed that patients with sarcoidosis have been misdiagnosed as TB based on a positive IGRA. There are few conflicting reports of IGRAs in sarcoidosis.[257] We have recently shown that IGRA (Quantiferon in tube^{r}) being more sensitive test than TST continues to remain positive in many patients with sarcoidosis and in high prevalence countries it should not be a deterrent for making a diagnosis of sarcoidosis, since it merely represents an underlying tubercular infection.[258]

Both tuberculosis and sarcoidosis can present with similar constitutional symptoms of fever, malaise, generalized aches, myalgias, easy fatigability and tiredness. Anorexia and weight loss may also occur. Respiratory symptoms of cough and breathlessness are common in both conditions. Chest tightness and wheezing may also occur. Expectoration and/or hemoptysis are distinctly more frequent in fibrocavitary tuberculosis, but can be occasionally present in fibrocystic sarcoidosis. In general, patients with untreated tuberculosis have more signs and symptoms compared to sarcoidosis. But the severity and magnitude may not always help in the differential diagnosis.

Although non-necrotizing granulomas are the usual findings in sarcoidosis, necrosis can occur. Prior to the widespread use of transbronchial biopsy necrosis was reported in up to 30% of large biopsy specimens (open lung, lymph node). The incidence of necrosis is far lower in small specimens such as transbronchial biopsies because of the small number of granulomas usually sampled. Compared with the "caseous" necrosis seen in TB granulomas, the necrosis in the granulomas of sarcoidosis is most often focal, very small in size and involves very few of the granulomas unrecognizable to the naked eye. The foci of necrosis are acidophilic with a fibrinoid, granular appearance and usually located within the centers of granulomas. Rarely, biopsy material from patients with well documented sarcoidosis will exhibit extensive necrosis.[103, 259]

The site and type of organ involvement may help in making a distinction. For example, lacrimal and parotid glands and myocardium are rarely involved in tuberculosis. Subtle differences which may help in differential diagnosis from tuberculosis are summarized in Table 96.5.

Finally, there are treatment issues to be considered in the relationship of sarcoidosis and tuberculosis. Reactivation of tuberculosis after corticosteroid treatment is instituted for sarcoidosis is a genuine concern, given the high prevalence of latent infection in our country.[261] If indeed tuberculosis is a causal factor in sarcoidosis, then the hypothesis can be further reinforced, if Antitubercular Therapy (ATT) is useful in the treatment of sarcoidosis. Very few trials have been conducted in the past, but the results of these trials have been discouraging. These trials were generally small studies and limited by time bias and used older regimens based on isoniazid, aminosalicylic acid and streptomycin.[262,263] In our experience, nearly one-third of patients who are finally diagnosed to have sarcoidosis, have received ATT for the variable length of time, but its impact of final outcome of sarcoidosis has not been studied. Role of antimicrobial therapy in sarcoidosis has recently been reviewed and it gives us a definite thought for the future research.[264]

TREATMENT

There are even more challenges in treating sarcoidosis than in diagnosing it. It is especially so in the developing countries, where the availability of medical expertise is limited, the referral system is insufficient and facilities to monitor efficacy and complications of treatment are inadequate. This is very true with reference to corticosteroid-treated patients who could be harboring mycobacteria in quiescent lesions.

When to Treat?[265-267]

Pulmonary Sarcoidosis

- Asymptomatic patient with bilateral hilar lymphadenopathy (Stage I) with or without erythema nodosum but without extrapulmonary involvement should be left untreated.[268,269]
- Patients with fever and joint pains respond to nonsteroidal anti-inflammatory agents. Occasionally, a short-term course of prednisone 15–20 mg/day may be needed to control symptoms that do not respond to anti-inflammatory drugs. Symptoms of cough and dyspnea may be associated with airway obstruction—even in this early stage—and should be treated with inhaled corticosteroids.
- Patients with bilateral hilar adenopathy and infiltration (Stage II) and symptoms (cough, dyspnea, chest pain and effort intolerance) should be treated. Spirometry, diffusing capacity, a chest radiograph

TABLE 96.5: Differentiating sarcoidosis form tuberculosis in high TB prevalence countries, some useful "INDICATORS"*

Indicator	*Sarcoidosis*	*Tuberculosis*
History of close contact with patient having tuberculosis infection	Not present	May be present
Constitutional symptoms	Asymptomatic or with mild fever, anorexia and loss of weight: Particularly with advanced radiological abnormalities "Patients walk-in"	More symptomatic and ill: "Patients are brought–-in"
Cough	Mainly dry, hemoptysis is rare	Usually productive, hemoptysis is common
Intrathoracic lymph node involvement	Typically symmetrical bi-hilar and paratcheal, smooth, discrete, and solid looking nodes	Asymmetrical, large, may be conglomerate, usually with central areas of hypodensity
Extrathoracic lymph node involvement	Seen in about 10% patients only	Cervical and axillary lymph node involvement is common
Lacrimal, parotid glands and myocardial involvement	May be seen	Rarely, if ever
Pleural, peritoneal, meningeal and adrenal involvement	Rarely, if ever (Fig. 96.12)	May be seen
Radiology: Necrotizing pneumonia, cavitation and pleural involvement with effusion	Rare	Common
HRCT scan of lungs (In case of diffuse involvement): Fig. 96.13	Micro and macro nodules which have characteristic distribution in peribronchovascular region, subpleural interstitium and interlobular septa	Micronodules, randomly distributed with tree-in-bud appearance
Clinico-radiological dissociation, i.e. patient relatively asymptomatic despite extensive pulmonary involvement	Often seen	Rare
Tuberculin test	*Nearly always negative*	*Nearly always positive*
Increased SACE level.	More common	Less common
Increased serum calcium or hypercalciuria	May be seen	Not seen
Sputum - Positive for *M. tuberculosis* on smear or culture	False-positive acid fast bacilli or rarely coexisting TB with sarcoidosis. Patient should never receive glucocorticoids alone	Confirmatory for TB
PCR of biopsy tissues is positive for *M. tuberculosis* DNA	Quantitative tests can be positive in up to half of the patients in high TB prevalence countries. Qualitative test show low copy numbers.[260]	Should be positive with high copy numbers if quantitative tests are done
Biopsy of involved site shows showing caseation necrosis (Figs 96.13A to D)	Noncaseating, compact granulomas, sparse lymphocytic cuffing around granuloma ('naked') with inclusion bodies at times	Caseating necrosis, ill formed granuloma with intense inflammatory reaction and may be positive for acid fast bacilli
No expected response to anti-tubercular therapy	Very common, however spontaneous resolution in sarcoidosis is known	Very rare, only in case of primary multidrug resistance
Dramatic clinical-radiological response to steroids	Usual	No response or may worsen

*These indicators are only based on common clinical observations with unknown sensitivity and specificity for most of them.

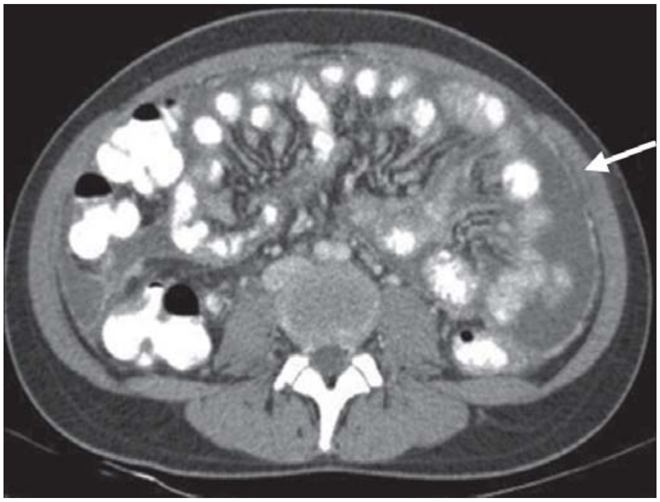

Fig. 96.12: Peritoneal sarcoidosis is rare and it resembles tuberculous peritonitis

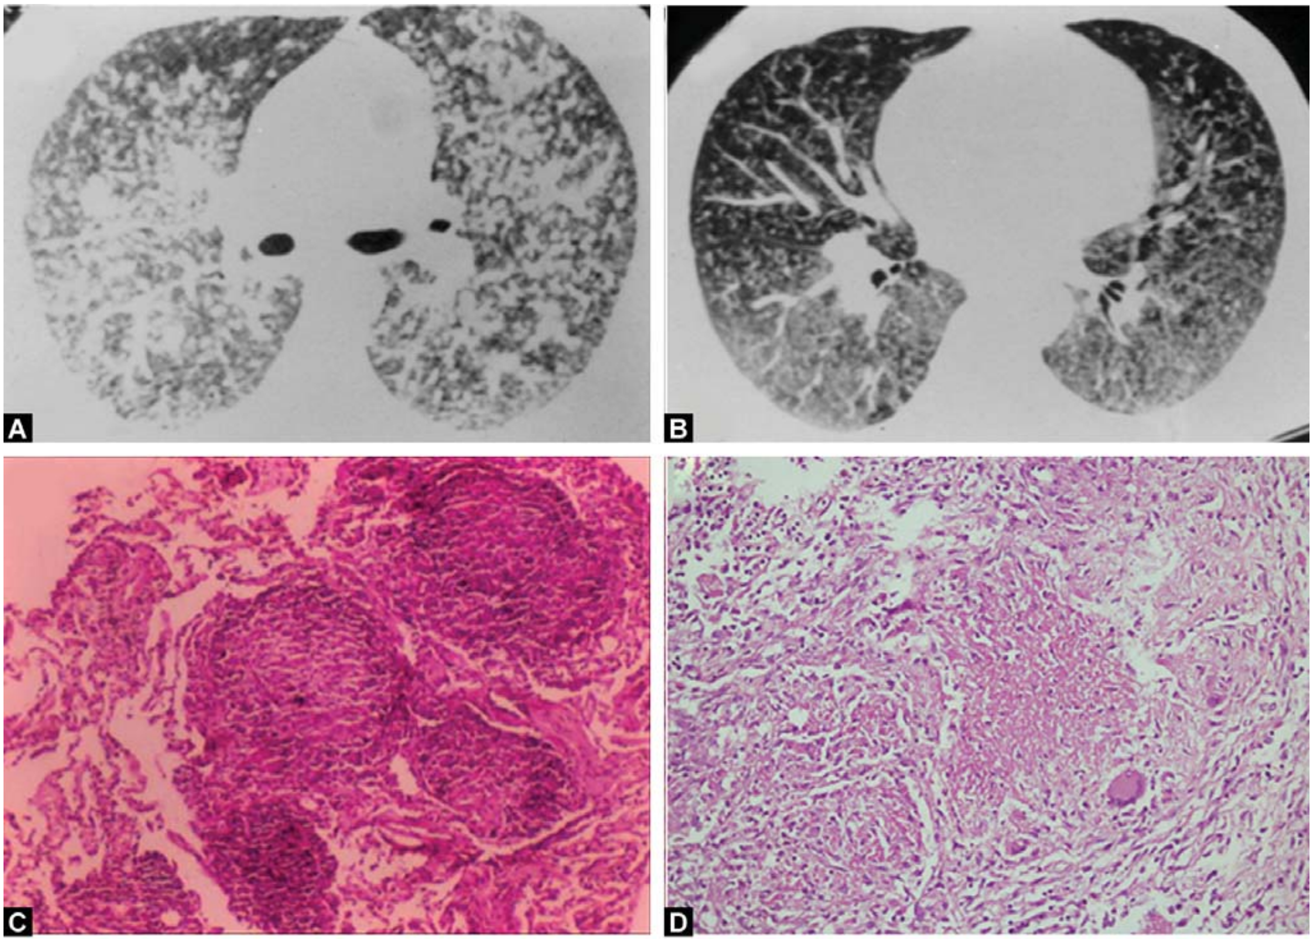
and serum ACE should be used to monitor the course of the disease.

- Patients with Stage II who are asymptomatic and have only mild lung function impairment can be followed without any specific treatment. However, if the deterioration of lung function should occur over a period of three to six months, the treatment should be instituted.
- Patients with Stage II who are asymptomatic with severe lung function impairment should be treated. Serial lung function measurement should be performed to establish the maximum response prior to tapering the drug to the maintenance dose.
- Patients with Stage III disease with diffuse pulmonary infiltration usually have symptoms along with lung function abnormalities and almost always need treatment. Asymptomatic stage III patients with



Figs 96.13A to D: Miliary sarcoidosis (panel A, C) versus miliary tuberculosis (panel B, D). On CT, the nodules in sarcoidosis are larger than tuberculosis with typical lymphangitic distribution. On histopathology, the granulomas in sarcoidosis are typically compact, with no necrosis and minimal lymphocytic cuffing (panel C) compared to the large areas of necrosis and intense lymphomononuclear cell infiltrates in tuberculosis (panel D)

progressive pulmonary function impairment may respond to corticosteroids because of the presence of reversible alveolitis intermingled with diffuse fibrosis.

- Stage IV diseases with extensive fibrosis and bullae formation respond poorly or not at all to corticosteroids and immunosuppressive therapy.[270] It should however be emphasized that some stage III and IV patients with irreversible fibrosis may have coexisting active alveolitis and the treatment should be strongly considered in order to control symptoms and functional impairment.[263] Some of the patients with stage IV disease are ideal candidates for lung transplantation. Bronchiectasis, hemoptysis and aspergilloma are treated conservatively with appropriate antibacterial and antifungal agents. An occasional patient with aspergilloma causing hemoptysis can benefit from intracavitary instillation of antifungal agents or arterial embolization. Resection may be necessary for severe hemoptysis if lung function is not severely impaired.

Extrapulmonary Sarcoidosis

Indications for the treatment of extrapulmonary involvement sarcoidosis are relatively straightforward. Ocular, neurologic, cardiac, upper airway involvement and hypercalcemia (Fig. 96.14) almost always need corticosteroids, often in higher doses (60 to 80 mg), and for a long time. Glandular involvement, splenic enlargement, parotid swelling and cutaneous lesions respond to modest doses of 20 to 30 mg daily. Asymptomatic hepatic involvement usually requires no therapy, but regular follow-up evaluation must be provided to exclude progressive impairment of liver function.

Choice of Drug

Corticosteroids

Corticosteroids have been in use for sarcoidosis since 1950s.[271] The steroids are potent anti-inflammatory agents and act by gene transcription leading to the inactivation of nuclear factor-kappa B, which inhibits the synthesis of most known cytokines. In a Cochrane database systematic review on the efficacy of corticosteroid in pulmonary disease, the authors concluded that oral corticosteroid therapy resulted in improvements in chest radiography, but evidence of a beneficial effect on lung function was limited.[272] Prednisolone, administered at a daily dose of 0.5 to 1 mg/kg body weight is effective in most patients. For pulmonary sarcoidosis, a lower dose of 20–40 mg/day is adequate as an initial dose.[273] Despite the paucity of high-quality data for corticosteroid therapy in sarcoidosis, experts in a recent Delphi paper[274] reached a consensus that corticosteroids are the initial therapy of choice and 40 mg of daily prednisone equivalent was the maximum dose recommended for the treatment of acute pulmonary sarcoidosis. The dose is tapered after a period to three to six months to a maintenance dose of 5–10 mg/day in patients responding to therapy with plans for the continuation of treatment for a minimum of 12 months with close monitoring for relapse.

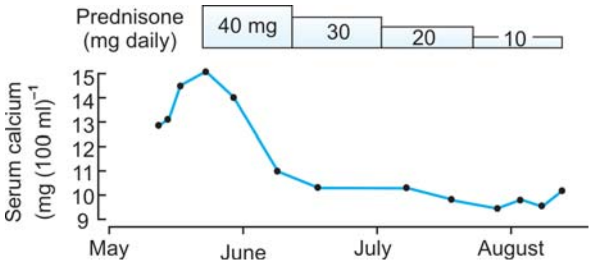


Fig. 96.14: Hypercalcemia in sarcoidosis responds to treatment with corticosteroids

There is insufficient data to recommend routine use of inhaled corticosteroids for the treatment of pulmonary disease.[275] A meta-analysis found inconclusive evidence to support the use of inhaled corticosteroids.[272] Isolated studies have demonstrated a slight improvement in diffusing capacity or improved symptoms.[276,277] Studies have also shown the use of inhaled budesonide after initial oral prednisone and in a placebo-controlled trial, 15 months of inhaled budesonide after three months of prednisone therapy was found to be superior at five-year follow-up for pulmonary function in the treated group.[278]

Corticosteroid therapy is associated with significant toxicity. The usual recommendation by the American Thoracic Society to undertake skin testing for latent tuberculosis before the initiation of corticosteroid therapy[279] is not practical for India for two reasons:

i. There is high prevalence of TB infection in population and a vast majority of our patients with sarcoidosis would be infected
ii. Tuberculin test is likely to be negative in active sarcoidosis (wide supra).

Another major complication of chronic glucocorticoid therapy is osteoporosis. Clinicians should consider calcium and vitamin D supplementation, after ruling out and monitoring of hypercalcemia and hypercalciuria. Use of bisphosphonate has been recommended by the American College of Rheumatology in patients receiving greater than 5 mg of prednisone per day or its equivalent for more than three months.[280] Other common side effects of corticosteroid therapy include increased risk of infection, hypertension, diabetes, mood changes, skin thinning, cataracts, acne and weight gain.

Alternate Drugs to Corticosteroids

Several alternate drugs to corticosteroids have been used by different investigators, often showing only modest benefits. Alternatives are required because of the side effects of corticosteroids and/or concomitant conditions such as diabetes mellitus, hypertension and other diseases which restrict the use of steroids. It is rather rare that sarcoidosis, diagnosed for the first time, does not respond to corticosteroids. Relapses however are refractory more commonly.

Cytotoxic Drugs

Cytotoxic drugs such as chlorambucil, methotrexate, cyclophosphamide and azathioprine constitute the most promising alternative to corticosteroids.[281-284] Methotrexate (MTX) is the preferred second-line drug and can be steroid sparing drug in acute sarcoidosis as well.[274,285,286] The typical dosage of MTX is 10–15 mg once a week often in combination with steroid therapy. The dosage may need to be adjusted for side effects, the most common of which are nausea and leukopenia. Response is relatively slower in onset. Although the clinical symptoms regress within two to four weeks, it takes about six to eight weeks for functional and radiological improvement. Both azathioprine and MTX have been also used as additional drugs to reduce the maintenance dose of prednisolone. A rational use of cytotoxic agents with the low doses of corticosteroids or other immune modifiers may enhance efficacy and reduce toxicity.[287] Careful monitoring is required for the toxicity of cytotoxic drugs with the help of repeated liver and renal function tests and hematological assessment.

Antimalarial Drugs

Antimalarial drugs such as chloroquine and hydroxychloroquine have been used with a fair degree of success, especially for cutaneous sarcoidosis.[288,289] Good response has also been reported in sarcoidosis of the upper respiratory tract,[290] sarcoidosis-related hypercalcemia[291] and neurosarcoid.[265] The typical dosing regimen for hydroxychloroquine is 200–400 mg daily. The risk of irreversible retinopathy and blindness greatly restricts its use for longer periods. This is significantly more likely with chloroquine than hydroxychloroquine, so hydroxychloroquine is the preferred agent. Rare side effects include agranulocytosis and myopathy, so periodic monitoring of the complete blood count and neuromuscular strength are recommended.

Tumor Necrosis Factor-Alpha Antagonists

Tumor necrosis factor-alpha antagonists, such as infliximab, adalimumab, are the latest entrant to this group of drugs. Since TNF-α is believed to play a central role in granuloma formation and inhibitors of this cytokine have been shown to be useful in several studies.[273,266-270,292-295] Besides several case reports and case series reporting clinical improvement in refractory neurosarcoidosis, cardiac sarcoid, cutaneous sarcoid, and sarcoid of the upper airway; two randomized trials have assessed the efficacy of infliximab therapy in pulmonary sarcoidosis and extrapulmonary therapy. In the pulmonary sarcoidosis there was an improvement in forced vital capacity,[293] whereas for extrapulmonary sarcoidosis although there was improvement after 24 weeks of therapy, but this benefit was not sustained after a 24-week washout.[266] Trials demonstrating long-term safety and efficacy of infliximab therapy are lacking. Of all the agents in this class, infliximab is the most studied, etanercept is not very useful and is not recommended for the treatment of sarcoidosis. Case reports of adalimumab are promising and this drug is under further investigation. Infliximab is typically given as an intravenous infusion of 3–5 mg/kg on weeks 0 and 2, with repeat dosing every four to eight weeks thereafter.[273]

One of the major concerns for the use of TNF-α inhibitors is the increased risk of the reactivation of latent tuberculosis and other opportunistic infections. In fact in the United States careful screening for latent tuberculosis and Isoniazid (INH) prophylaxis for all those found positive is recommended for all patients planning to start therapy with a TNF-α inhibitor,[296] a recommendation that is not possible to implement in countries with the high burden of tuberculosis. Therefore, the role of these therapies for the treatment of sarcoidosis in India would remain limited to a few carefully selected patients, where other therapies fail.

Other known side effects include a possible increase in malignancy, such as lymphoma, new onset and worsening of congestive heart failure, and demyelinating diseases. Surprisingly, there are also several reports of development of sarcoidosis during treatment with TNF-α antagonists, which represents a rare and paradoxical adverse event. The occurrence of sarcoidosis has been reported with all three available agents and is probably linked to a cytokine disequilibrium.[297]

Several other drugs which have been employed in sporadic cases or short trials include leflunomide, mycophenolate, colchicine, pentoxifylline and cyclosporin A. None has found an established role as yet.[281,298]

How Long to Continue?

The duration in each patient is individualized on the basis of symptoms, organ involvement and response to therapy. There is frequent relapse of symptoms when the treatment is tapered off.[299-302] Prolonged treatment is recommended for the continued suppression of disease-activity. Most clinicians continue treatment for about one year.[3,269] Significantly better results were observed in patients who had received prolonged treatment for four years or more in the BTS study.[268]

There is a small group of patients with limited but symptomatic disease in whom the treatment is discontinued after a period of three to six months. On the other hand, some of the patients may require low-dose prednisolone treatment for much longer periods of 10 years or more. Alternate day treatment is preferred if required for longer periods. It is considered safer than the daily dose regimen, even when the total dose is similar.[303] Recently, it was shown that treatment of acute exacerbations of pulmonary sarcoidosis with 20 mg prednisone for a median of 21 days improved spirometry back to baseline and improved clinical symptoms.[304]

The status of long-term treatment in developing countries is somewhat depressing.[117] There is a general trend to taper treatment earlier than required, largely for the fear of steroid-induced complications and poor patient compliance. Patients often stop treatment on their own and report back only when symptoms relapse. It is not infrequent to encounter patients who have received multiple courses of steroid treatment for short periods.

Treatment of Complications

Management of complications of disease, different treatments and associated conditions is also important. Steroid-induced complications are frequent and have been discussed above.

Systemic, constitutional symptoms of sarcoidosis are treated with analgesics and nonsteroidal anti-inflammatory drugs. An often overlooked aspect of sarcoidosis is fatigue. Regardless of disease activity, patients often report fatigue, sleep disturbance, and impaired general Quality of Life (QOL),[305] one study had shown good results with use of dexmethylphenidate hydrochloride for the treatment of sarcoidosis-associated fatigue.[306] Sarcoidosis patients should be screened for depression.

Bronchiectasis requires treatment like any other bronchiectasis patient, with anti-inflammatory therapy, postural drainage, and appropriate antibiotic therapy for exacerbations.[307] Extensive fibrosis causing hypoxemia requires supplemental long-term oxygen therapy. Additional treatments for complications due to extrapulmonary organ involvement are needed as appropriate. Decongestive therapy is required for heart failure due to sarcoid cardiomyopathy. Radiation therapy has been successfully used for refractory neurosarcoidosis.[308] Recently, bronchoscopic balloon dilation with adjunctive topical mitomycin-C has been tried in broncostenosis following sarcoidosis.[309] Elderly sarcoidosis patients often present with the unusual clinical features of sarcoidosis. Occasionally, these features resemble malignancy; rarely sarcoidosis and malignancy may coexist.[310]

With severe functional impairment and patient disability, pulmonary hypertension and right heart failure may supervene for which the patient will require oxygen and careful dieresis. Sildenafil and bosentan are effective for pulmonary hypertension .[311] These patients are candidates for Lung Transplantation (LT). Survival rates following LT for sarcoidosis are generally comparable to other indications. Recurrent sarcoidosis in the lung allografts can occur but does not affect survival or risk for complications.

PROGNOSIS AND MORTALITY

Sarcoidosis is a benign process. Many patients remain asymptomatic and spontaneous remission is common. The disease however follows a chronic course in 10% to 30% of the cases, sometimes leading to significant deterioration in lung function. Mortality rates of 1% to 6% have been reported.[312] Fibrosis in the chest radiograph and a forced vital capacity below 1.5 L are predictive of death due to respiratory failure caused by sarcoidosis.[313] When fibrosis and pulmonary hypertension are present at the same time, there is a sharp drop in respiratory functions and such findings should alert the clinician to this serious complication.[314] In the survival analysis, sarcoidosis has a better prognosis at five years (91.6% survival) compared to other diffuse interstitial lung diseases such as nonspecific or desquamative interstitial pneumonia (85.5%), hypersensitivity pneumonitis (84.1%), collagen-related diffuse interstitial lung disease (69.7%), undefined forms of pulmonary fibrosis (69.5%), and idiopathic pulmonary fibrosis (35.4%).[313] Only one case-control study points to a possible increased risk for developing neoplastic processes, such as lymphomas, lung cancer, or cancer of other organs affected by the disease, but these findings have not been confirmed in other studies with long-term follow-up.[315,316] In short, the prognosis of sarcoidosis is linked to the severity of the disease.

FUTURE DIRECTIONS

Despite extensive research, sarcoidosis remains an enigmatic disease. A working group of the National Heart, Lung, and Blood Institute identified several future research directions and opportunities for sarcoidosis. These include developing a tissue bank, using novel methods to identify genetic factors, studying the immunopathogenesis with human tissue and animal models, exploring new approaches to diagnose and manage disease, and, finally, conducting randomized controlled trials to assess new therapies.[317] The remarkable similarity of sarcoidosis to tuberculosis and the continued interrelationship of the two conditions is of special interest to clinicians and researchers from countries with ongoing TB epidemic. The wish list for sarcoidosis research in these countries would therefore include the development of definitive test/s for differentiating the two conditions and also looking for newer therapies or standardizing the existing treatments in a fashion that would reduce the risk of common complications such as the reactivation of latent tuberculosis.

Pulmonary Eosinophilic Disorders

Subhash Varma, Aditya Jindal

INTRODUCTION

Though eosinophils were first described by Paul Ehrlich in 1879,[1] Löeffler described the association between pulmonary infiltrates and eosinophilia in 1932[2] and the term "Pulmonary Infiltrates with Eosinophilia" (PIE) was coined by Reeder and Goodrich in 1952.[3] It has been just over 30 years that the role of these cells in the etiopathogenesis of systemic disease, including that of the lungs, has been better understood and defined.

Eosinophilia and lung disease is currently recognized to be either secondary to known causes or a primary involvement. Eosinophilic lung disease, therefore, includes conditions known to involve the lung that are associated with peripheral and/or pulmonary eosinophilia.

Eosinophils

Eosinophils originate from CD34+ myeloid progenitor cells and share a common immediate precursor with basophils that differentiate towards the eosinophilic lineage under the influence of various cytokines, mainly Interlukin-5 (IL-5), GM-CSF and IL3. Expression of high affinity IL-5 receptor is a prerequisite and an early lineage specific event in this process. Interleukin-5 gene knockout mice produce basal levels of eosinophils; however do not mount expected blood and/or tissue eosinophilia in response to various stimuli. Interlukin-5 is produced by T cells and endothelial cells in the bone marrow, and T cells and parenchymal cells in the lung. Along with the differentiation of eosinophils it also promotes the release of eosinophils into the bloodstream.

Mature eosinophils are characterized by the presence of large membrane limited granules that have an electron dense core and that of small granules. The core of large granules is formed by Major Basic Protein (MBP) while the matrix contains various other enzymes such as Eosinophil-Derived Neurotoxin (EDN), Eosinophil Cationic Protein (ECT) and eosinophil peroxidase. The smaller granules have enzymes like arylsulfatase and acid phosphatase. In addition, dense lipid bodies that are not membrane bound and contain enzymes for metabolizing arachidonic acid, serving as sites of eicosanoid synthesis, are present.

Following its release, the mature eosinophil enters various tissues predominantly those having an epithelial-environment interface such as respiratory, gastrointestinal and genitourinary tracts after a brief intravascular stay. It is eventually phagocytosed by tissue macrophages after a few days. Once in tissues, their survival depends upon the local production of cytokines regulating eosinophil apoptosis. Eosinophils have a diurnal variation in response to the level of endogenous steroids with higher levels in the morning.[4] Pyogenic infections lead to eosinopenia, while parasitic infestations and drugs cause eosinophilia. Eosinopenia can also occur in response to exogenous steroids, estrogens and epinephrine.[5,6]

Circulating eosinophils, like other leukocytes, first move to the margins of the blood stream where, by the process of rolling, they adhere to the vascular endothelium. These then enter the interstitium by passing in between the endothelial cells by diapedesis and then under the influence of various cytokines and chemokines to the site of inflammation. After their arrival, they are

TABLE 97.1: Defining limits of eosinophilia

Normal counts: Differential: $\leq 5\%$
AEC: $\leq 0.5\times10^9$/l

Eosinophilia:

- Mild: AEC $0.5\text{-}1.5\times10^9$/l
- Moderate: AEC $1.5\text{-}5.0\times10^9$/l
- Severe: AEC $>5.0\times10^9$/l

HES: (Chusid et al[7])

- AEC: $>1.5\times10^9$/l lasting for 6 months
- Lack of evidence for known causes of eosinophilia
- Signs and symptoms of organ involvement/dysfunction

primed by cytokines, especially IL-5, platelet activating factor and complement fragment of C5a. This results in the release of various mediators that include MBP, Eosinophil Cationic Protein (ECP), EDN, Erythropoietin (EPO), substance P and also oxygen radicals, lipid mediators and cytokines like IL1, IL3, IL5, IL6, IL8, GMCSF, TGF α and β, eotaxin, the prostaglandins, leukotrienes and platelet-activating factor that finally contribute to the inflammatory actions of the eosinophils.

The role of eosinophils in allergic disorders, parasitic and neoplastic diseases, tissue inflammation or idiopathic eosinophilia as a result of their proinflammatory and cytotoxic effects is now better understood. As discussed, these effects are related to preformed granule constituents and inducible lipid mediators, cytokines and oxidative products. The role of eosinophils in tissue injury has been elucidated by demonstration of both enzymatic and nonenzymatic cationic protein constituents of primary and secondary granules in the tissues involved in eosinophilia related disorders. A large number of conditions are associated with the development of variable levels of eosinophilia (Table 97.1) with manifestations in different organ systems necessitating a careful search for the cause. Though secondary causes of eosinophilia are more likely (allergic disorders in the west and parasitic infections in rest of the world) in many cases, an underlying myeloid malignancy may be detected (clonal eosinophilia); the search may be inconclusive in several instances and lead to a diagnosis of idiopathic Hypereosinophilic Syndrome (HES). As a part of the human leukocyte system, eosinophils have a variety of functions to perform. They are especially important in the defense against helminthic infestations—eosinophilic products are lethal to the larval stages of these parasites.

TABLE 97.2: Pulmonary eosinophilic disorders

- **A. Primary pulmonary eosinophilia**
  1. Predominant involving lung
     - Acute eosinophilic pneumonia
     - Chronic eosinophilic pneumonia
  2. Systemic disease with lung disease
     - Churg-Strauss syndrome
     - Idiopathic hypereosinophilic syndrome
- **B. Secondary pulmonary eosinophilia**
  1. Infections
     - Parasitic infestations
  2. Transient passage (Löffler's syndrome):
     - Ancylostoma, ascaris, strongyloides
     - Tissue resident: paragonimiasis, echinococcosis
     - Heavy hematogenous seeding
       - Trichinella
       - Visceral larva migrans
       - Disseminated strongyloidiasis
       - Schistosomiasis
     - Fungal infections: Coccidiomycosis, Histoplasmosis
     - Other infections: Tuberculosis, Brucellosis
  3. Tropical pulmonary eosinophilia
  4. Allergic bronchopulmonary aspergillosis
  5. Hypersensitivity pneumonia
  6. Drugs, toxins and radiation
- **C. Lung disorders with associated eosinophilia**
  1. Interstitial lung disease
     - Sarcoidosis
     - Idiopathic pulmonary fibrosis
     - Langerhans cell histiocytosis
     - Connective tissue disease
  2. Asthma
  3. Bronchiolitis obliterans-organizing pneumonia
  4. Neoplastic disorders
     - Hematological malignancies
     - Solid organ tumors
  5. Postlung transplant

PULMONARY EOSINOPHILIC DISORDERS

Pulmonary eosinophilic disorders may occur with or without a known cause or as an association of known lung disease (Table 97.2). Since many of these disorders have been dealt with in details elsewhere (Chapter 75—Allergic Bronchopulmonary Aspergillosis, Chapter 62—Parasitic Lung Diseases, and Chapter 64—Bronchial Asthma), we shall restrict the discussion primarily to that of primary pulmonary eosinophilic disorders [Acute Eosinophilic Pneumonia (AEP), Idiopathic Chronic Eosinophilic Pneumonia (ICEP), Churg-Strauss Syndrome (CSS) and HES] and those related to drugs and toxins.

Acute eosinophilic pneumonia and ICEP are only occasionally associated with extrapulmonary involvement and predominant systemic symptoms suggest the possibility of systemic vasculitis, idiopathic HES or other causes. A brief mention of Löffler's syndrome is needed in this review because since its first description by Löffler in 1932,[8] it is recognized that the exact cause of simple pulmonary eosinophilia is not determined in a substantial number of cases. A similar syndrome may be seen secondary to drug reaction. There is no age or sex predilection and the patients typically present with an acute, self limiting disease comprising of low-grade fever, dry cough, dyspnea and rarely, hemoptysis. Blood examination shows moderate to marked eosinophilia; respiratory secretions may also show eosinophilia. The chest X-ray will show transient, migratory, nonsegmental interstitial or alveolar infiltrates. The symptoms typically resolve within one to two weeks.

Acute Eosinophilic Pneumonia

Acute eosinophilic pneumonia is an acute onset rapidly progressive disorder that occurs in the previously normal young adult population and causes acute onset, severe respiratory failure.[9,10] The median age at onset is approximately 30 years, has slight male preponderance.[11] The exact cause is not known though it has been associated with unusual activities such as cave exploring and wood working. This has led to a hypothesis that AEP is due to a hypersensitivity reaction to fungal antigens; nothing has been proven as yet. Also, cases have been reported in individuals who have recently taken up smoking.[12]

The clinical presentation is acute with rapid progression to Acute Respiratory Distress Syndrome (ARDS) within two to three days. Patients may present with fever, cough, myalgias, dyspnea, pleuritic chest pain that progresses to frank respiratory failure with ARDS. A somewhat characteristic feature is the absence of any multisystem involvement despite severe respiratory failure.[11]

Investigations typically show leukocytosis with initial absence of peripheral blood eosinophilia, though the IgE levels may be moderately increased. The chest X-ray shows bilateral patchy infiltrates that progress rapidly to ARDS like picture with diffuse alveolar or interstitial infiltrates. The Computed Tomography (CT) scan shows diffuse parenchymal opacities.[13] Bilateral pleural effusions may also be seen, pleural fluid analysis shows marked eosinophilia and high pH. Bronchoalveolar Lavage (BAL) shows marked eosinophilia along with variably elevated levels of beta-D-glucan and many cytokines such as IL-5 and IL-18. Pulmonary function tests during the acute phase show a restrictive defect with reduced DL_{CO}.

Despite its severe clinical presentation, AEP is highly responsive to corticosteroids. The mortality rate is low with prompt treatment that results in a rapid and sustained response and infrequent relapses. The diagnosis requires a high index of suspicion and is made only after exclusion of all other causes.

Idiopathic Chronic Eosinophilic Pneumonia

ICEP was first described by Carrington in 1969.[14] Though it may occur at any age, the peak incidence of the disease is seen between the ages of 30–40 years[15] with a slight female preponderance.

Patients with CEP are generally nonsmokers. A history of antecedent atopy, allergic rhinitis or nasal polyps is present in one-third to half of the patients and that of asthma in about two-third of the patients. The asthma is adult onset and may arise spontaneously or precede ICEP by some time.

The clinical picture is that of an insidious onset and indolent course.[16] Predominant symptoms are low-grade fever, drenching night sweats and weight loss. Associated cough either productive or nonproductive, dyspnea and wheezing are the other presenting features. Dyspnea is generally mild, but at times may progress to a point that mechanical ventilation may be required. Extrapulmonary manifestations other than fever, asthenia and weight loss occur rarely include arthralgias, joint pains and heart failure.

Diagnosis

The peripheral blood examination shows normocytic-normochromic anemia with a mild to moderately elevated Erythrocyte Sedimentaion Rate (ESR). There is usually a moderate leukocytosis with eosinophils constituting less than 30%.[17] However, the absence of peripheral eosinophilia should not preclude the diagnosis. BAL fluid also shows marked eosinophilia ranging from 12 to 95% of the total. Serum IgE levels are moderately elevated in about half of the cases. Pulmonary function testing may either be normal or show an obstructive or restrictive defect. The obstructive defect may occur in patients with asthma though patients without asthma may also develop the same. The restrictive pattern occurs due to eosinophil infiltration into the interstitium. The DL_{CO} will be mildly reduced.

The radiographic features of CEP are quite variable. Characteristically, infiltrates are progressive, bilateral, peripheral and symmetrical that gives an X-ray appearance of the photographic negative of pulmonary edema and disappears with corticosteroid therapy.[18] The infiltrates are usually dense, patchy, irregular opacities which involve the upper and mid zones. They may be subpleural in location. The characteristic "photographic negative of pulmonary edema" that occurs following involvement of extensive areas or whole lung is seen in less than 25% of cases.[19] Pleural effusions are uncommon. HRCT shows more bilateral involvement similar with areas of ill-defined consolidation and ground glass opacification, areas of patchy consolidation with atelectasis and septal thickening. There may be mediastinal lymphadenopathy and nodular infiltrates.

Histopathologic examination reveals infiltration of the interstitium and the alveoli by eosinophils, lymphocytes, macrophages and plasma cells with disruption of the local architecture. Evidence of proliferative bronchiolitis obliterans, microangiitis and microabscesses may also be seen. The diagnosis is suggested by appropriate investigations in the presence of a suitable clinical background. The differential diagnosis includes tuberculosis, fungal infections (like cryptococcosis), sarcoidosis, Löffler's syndrome, Desquamative Interstitial Pneumonia (DIP) and Bronchiolitis Obliterans with Organizing Pneumonia (BOOP), among others.

Management

There is a dramatic response to corticosteroids in CEP with symptoms decreasing within 6 to 48 hours and radiological clearing within two months. Oral steroids in usual doses can be used and treatment in low doses is maintained for at least six to nine months or longer. Relapse occurs in up to half of treated patients after discontinuation of steroids.[16] However, currently no risk factors indicative of relapse are recognized. The relapse can usually be controlled by reinstitution of steroids which may need to be given for prolonged periods of time.[17,19-22]

Churg-Strauss Syndrome (Allergic Granulomatosis and Angiitis)

Churg-Strauss syndrome was first described as a separate entity in the early 1950s.[23,24] It is an uncommon disease and its diagnosis is often missed or delayed. It can affect any age group with peak incidence between 30 and 50 years, without any sex predeliction.[25] The underlying pathology is believed to be an immune hypersensitivity, accounting for the presence of Antinuclear Cytotoxic Antibodies (ANCA) and nearly universal finding of an atopic state in these individuals.

Churg-Strauss syndrome has also been associated with the use of leukotriene inhibitors, montelukast more than zafirlukast.[26] The onset of the disease is variable from 2 days to 12 months after the initiation of therapy and it occurs almost exclusively as corticosteroids are being tapered off. This is considered to be an unmasking of the underlying disease rather than the result of drug use.

Clinical Features

Churg-Strauss syndrome can be divided into three stages, clinically:

1. *Prodromal stage:* This can last for months to years. The patient usually presents with late onset atopic states such as allergic rhinitis, nasal polyposis and asthma in the absence of any family history.
2. *Eosinophilic stage:* This stage is characterized by the infiltration of various tissues by eosinophils, especially the skin, gastrointestinal tract (GIT) and lungs.
3. *Vasculitic stage:* Characterized clinically by the onset of constitutional symptoms and microscopically by eosinophilic infiltration, vasculitis and granulomatous infiltration.

The respiratory manifestations of CSS include upper respiratory tract disease, asthma, pleural effusions and Löffler's like syndrome. The upper respiratory tract is involved in approximately 75 to 85% percent of cases and manifests as allergic rhinitis, sinusitis and nasal polyposis. No necrosis is seen unlike in Wegener's granulomatosis.[27]

Asthma is the predominant feature of CSS. It may be present for many years before the diagnosis of CSS is made.[28] It is usually predominant in the prodromal and eosinophilic stages of the disease and may subside with the onset of the vasculitic phases. A short interval between the onset of asthma and that of vasculitis is considered a sign of increased severity.[29]

Other pulmonary manifestations include a Löffler's like syndrome (40%) and unilateral or bilateral pleural effusions or pleurisy without effusions in up to one-third of patients.

The cardiovascular system is commonly involved and is the leading cause of mortality.[25] Patients may develop coronary vasculitis leading to myocardial infarction[25] and ischemic cardiomyopathy or congestive cardiac failure secondary to eosinophilic myocardial infiltration. Acute and chronic constrictive pericarditis and pericardial tamponade may also occur. The development of coronary vasculitis is associated with high risk of mortality of around 60%.[30]

Systemic manifestations may be prominent, include fever, weight loss, arthralgias and arthritis, lymphadenopathy, splenomegaly, urological and ocular disease.

These generally herald the onset of extrapulmonary disease. Neurological manifestations are seen in up to two-third of patients, include mononeuropathy and polyneuropathy, cranial neuropathy especially optic neuritis, mononeuritis multiplex, seizures, cerebrovascular accidents and subarachnoid hemorrhage.[28]

Gastrointestinal tract manifestations generally consist of eosinophilic gastroenteritis or vasculitis causing abdominal pain, bleeding, diarrhea, intestinal obstruction, bowel perforation, gastric ulcers and liver function test abnormalities.[31] Dermatologic manifestations like palpable purpura, nodules, ulcers, maculopapular rashes and livedo reticularis may occur. Renal involvement consists of interstitial nephritis, focal segmental glomerulosclerosis, hematuria and hypertension following renal infarction. However, chronic renal failure is unusual in CSS as compared to other forms of vasculitis.

Diagnosis

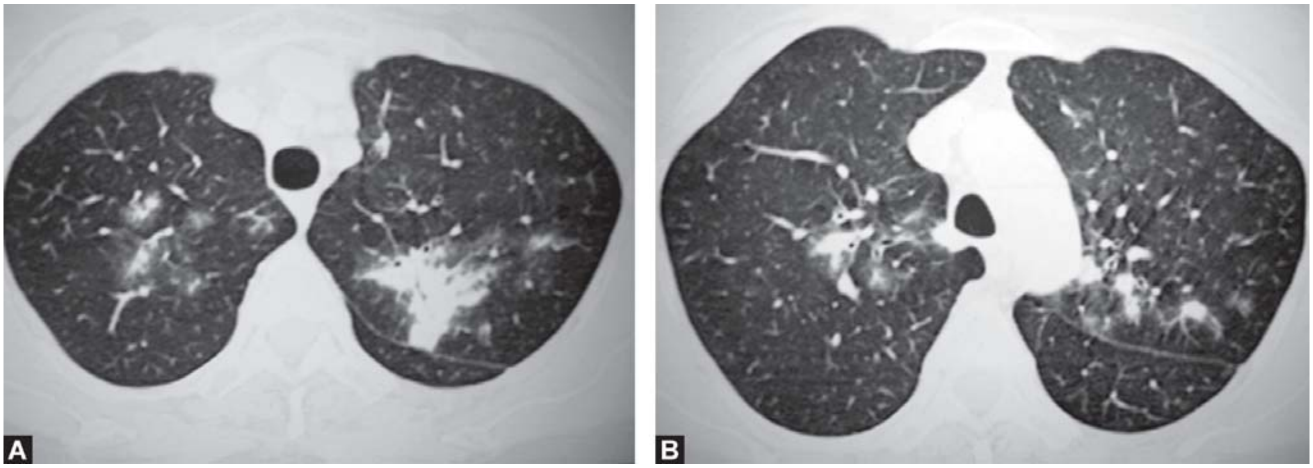
Laboratory examination shows normocytic-normochromic anemia, normal platelet counts and a high ESR. Leukocytosis with variable eosinophilia is commonly noted. Immunoglobulin E (IgE) and IgG levels are elevated and there is hypergammaglobulinemia with rheumatoid factor seropositivity. Immunoglobulin E levels may parallel the disease activity. About two-third of patients have pANCA positivity[31,32] that does not have utility as a marker of disease activity on follow-up examinations.

The chest X-ray may be normal or nonspecific. Löffler's syndrome like infiltrates may be present in up to 40% of individuals (Figs 97.1A and B) and pleural effusions may be seen in one third of cases. Other findings on radiology include noncavitatory nodules, patchy areas of consolidation or ground glass opacification, septal thickening, pulmonary artery enlargement and peribronchial thickening.[25] Pleural fluid is acidic with high eosinophil count and low glucose levels.

Pulmonary function tests show an obstructive physiology while BAL shows variable eosinophilia. Positron Emission Tomography (PET) may show cardiac involvement. Histopathological examination of various tissues, including the lungs, pleura, skin, GIT and nervous tissue reveals both intravascular and extravascular noncaseating granulomas with eosinophilic infiltration accompanied by vasculitis of the small and medium-sized arteries, veins, venules and capillaries.[25] These features give the disorder eponym "Allergic granulomatosis with angiitis." The inflammation may resolve with time and treatment, or lead further to fibrous scarring.

In the absence of universally accepted diagnostic criteria, the diagnosis of CSS is challenging. There are several diagnostic criteria that rely on symptoms of asthma, eosinophilia and evidence of organ involvement secondary to medium and small vessel vasculitis. The American College of Rheumatology criteria published in 1990 require the presence of at least four out of the six given criteria, which give a sensitivity and specificity of 85% and 99.7%, respectively.[33] These include i) asthma, ii) paranasal sinusitis, iii) monoarthropathy or polyarthropathy, iv) migratory or transient pulmonary infiltrates, v) peripheral blood eosinophilia greater than 10%, and vi) extravascular eosinophils in a blood vessel on a biopsy specimen.

The differential diagnosis includes Wegener's granulomatosis, polyarteritis nodosa, tuberculosis, fungal infections, allergic bronchopulmonary aspergillosis,



Figs 97.1A and B: HRCT of a patient with CSS with pulmonary infiltrates

chronic eosinophilic pneumonia, asthma and Hodgkin's disease.

Treatment

The treatment includes corticosteroids and cytotoxic medications.[28,30] Corticosteroid use is indicated in patients with systemic involvement, hypertension and lung involvement. Oral prednisolone may be started at a dose of 60–100 mg per day and continued for 6–12 weeks followed by a gradual taper to a maintenance dose, which might be continued for a year or more. Disease activity may be followed by the disappearance of constitutional symptoms, hypertension, cardiac, renal, neurological and vasculitic disease. Laboratory markers of disease activity include ESR, IgE levels and leukocyte counts; pANCA is not useful for follow-up.

Indications for the use of cytotoxic chemotherapy include nonresponsiveness to steroids and severe systemic disease including cardiac, GIT and renal disease (proteinuria >1g/day or renal insufficiency). Pulse cyclophosphamide is probably the immunosuppressive treatment of choice in an acute phase, whereas azathioprine may be useful for maintenance. Other immunomodulators such as high dose intravenous immunoglobulin and interferon-alpha in standard dose have also been used in severe disease and so has been plasma exchange.[28] Beta blockers use to control hypertension should be avoided since it could precipitate congestive cardiac failure and bronchospasm.

The prognosis of CSS is very poor without treatment. However, the use of corticosteroids has dramatically reduced the mortality rate.[28] Long-term remissions are usually achieved, though relapses may occur.

Hypereosinophilic Syndrome (HES)

It is also known as Löffler's endocarditis and eosinophilic leukemia. Hypereosinophilic syndrome is a disorder characterized by multisystem involvement and a variation in the severity of presentation.[7,34-36] It predominantly affects males and is more common from 20–50 years, though it can occur at any age.[34] The diagnostic criteria, initially proposed by Chushid have been subsequently expanded to include the World Health Organization (WHO) criteria for diagnosis (Tables 97.1 and 97.3).[7,37] There has been a significant confusion in the past over the terminology and at times it was thought that HES constitutes a spectrum of illness with minimal involvement on one hand and eosinophilic leukemia on the other extreme. Recent WHO classification suggests that clonal disorders that show chromosomal or molecular clonality should be classified as neoplastic and HES should include the rest of the disorders without any clear cause for eosinophilia.

TABLE 97.3: WHO criteria for diagnosis of chronic eosinophilic leukemia and hypereosinophilic syndrome[37]

- Persistent eosinophilia $>1.5\times10^9$/l
- Increased number of eosinophils in the bone marrow
- Myeloblasts <20% in both blood and bone marrow

1. Exclude all causes of reactive eosinophilia (secondary to allergy, parasitic diseases, infectious diseases, pulmonary diseases, collagen vascular diseases etc.)
2. Exclude all neoplastic disorders with reactive eosinophilia (T-cell lymphomas, Hodgkin's lymphoma, ALL, B-cell lymphomas, mastocytosis)
3. Exclude other neoplastic disorders in which eosinophils are part of neoplastic clone [Philadelphia (Ph) chromosome &/and/or BCR-ABL positive chronic myelogenous leukemia; acute myeloid leukemia, including those with inv(16), t(16;16)(p13;q22); other myeloproliferative diseases like Polycythemia Vera (PV), Essential Thrombocythemia (ET), Idiopathic Myelofibrosis (IMF)]
4. Exclude T cell populations with aberrant phenotype and abnormal cytokine production
5. Diagnose HES if there is no demonstrable disease that can cause eosinophilia, no evidence of abnormal T cell population and no evidence of clonal myeloid disorder
6. Diagnose CEL if all of the requirements (including conditions 1–4) have been met, and if the myeloid cells demonstrate a clonal cytogenetic abnormality or are shown to be clonal by other means, or if blast cells are present in peripheral blood (<2%) or BM (5%–19%)

The cause of this disorder is unknown and the various hypotheses propose it as a disorder ranging from a primary disturbance of myelopoiesis to a monoclonal expansion of T lymphocytes producing cytokines to an immune hypersensitivity reaction. The organ damage is the result of eosinophilic infiltration and/or thromboembolic phenomena.

Clinical Features

Three major clinical variants of HES are recognized[38] myeloproliferative variant, lymphoproliferative and the familial HES. The myeloproliferative variant has been shown to be associated with FIP1LI-PDGFR α fusion gene. Since these patients have a clonal abnormality, these may also be classified by some as chronic eosinophilic leukemia. The lymphoproliferative variant is associated with monoclonal expansion of T cells that result in increased IL-5 secretion and hypereosinophilia. Familial HES is secondary to genetic defect that results in increased IL-5 and eosinophilia. Currently, even after detailed investigations, a subset of patients may not reveal any cause, termed as true idiopathic HES.

Hypereosinophilic syndrome is a heterogeneous disease. Its clinical manifestations are also highly variable in the terms of duration, severity and organ involvement. The symptoms most often are indolent; include fever, weight loss, fatigue, anorexia, night sweats, skin rash, hepatosplenomegaly, angioedema and other system involvement.

The respiratory system is involved in approximately 40% of cases, manifested predominantly by nocturnal cough, which is usually nonproductive.[7,36,38] Wheezing and dyspnea also occur and occasionally the disease can progress to ARDS. Pleural effusion, pulmonary hypertension and thromboembolism may develop over a period of time.

The cardiovascular system is most commonly involved.[34,39] There is an eosinophilic infiltration of the endocardium and myocardium leading to restrictive cardiomyopathy,[40,41] endocardial fibrosis and mitral regurgitation. Intracardiac thrombus formation occurs, leading to pulmonary thromboembolism. Associated peripheral arterial or venous thrombosis has also been reported.[42]

Neurological manifestations include encephalopathy, neuropsychiatric disturbances, memory loss, visual changes and cerebrovascular accidents secondary to thromboembolism.[43] Other systems are involved less frequently; the symptomatology varies according to the system involved (Table 97.4).

Diagnosis

Blood examination shows anemia, leukocytosis (10,000–50,000/mm^3) with 30 to 70% eosinophils. Erythrocyte sedimentaion rate, serum IgE and gamma globulins are elevated. Also noted are elevated levels of serum B$_{12}$ and leukocyte alkaline phosphatase. Circulating immune complexes are occasionally found. Bone marrow shows an increase in eosinophils and eosinophil precursors (Fig. 97.2). Eosinophilic blast transformation has been noted in 28 to 51% of patients. Eosinophilic infiltration of other organs is also demonstrable on histopathological examination (Fig. 97.3).

TABLE 97.4: End-organ damage in HES and hypereosinophilic disorders

Cardiac	Pericarditis, EMF, cardiomyopathy, myocarditis, intramural thrombi, regurgitation
Neurologic	Thromboemboli, peripheral neuropathy, dementia/psychosis, meningitis, epilepsy
Dermatologic	Angioedema, urticaria, papulonodular lesions, mucosal ulcers, vesiculobullous, microthrombi, Raynaud's phenomenon, digital necrosis
Pulmonary	Infiltrates, fibrosis, effusion, emboli
Ocular	Microthrombi, vasculitis, retinal arteritis
Joints	Arthralgia, effusions, polyarthritis
Gastrointestinal	Ascites, diarrhea, gastritis, colitis, pancreatitis, cholangitis, Budd-Chiari syndrome

Chest X-ray shows focal or diffuse nonspecific infiltrates and pleural effusions. Pulmonary function tests demonstrate an obstructive physiology. Echocardiography may show evidence of intracardiac thrombi, should be done six monthly in follow-up as cardiovascular disease is the major cause of mortality and morbidity in this disease.[42]

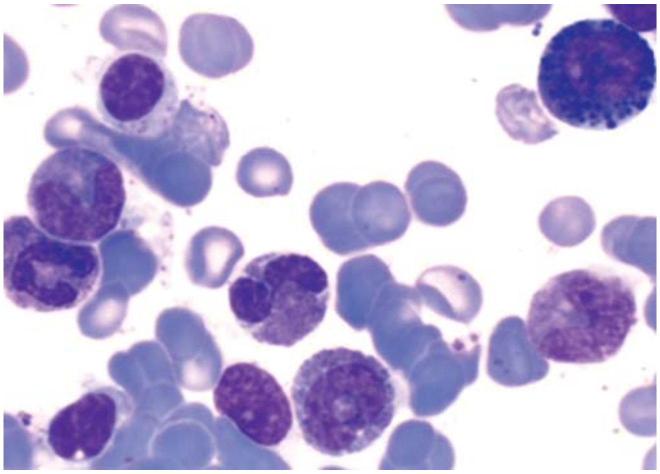


Fig. 97.2: BM smear in HES patient showing two metamyelocytes, one basophil and two eosinophils (one has a ring nucleus)

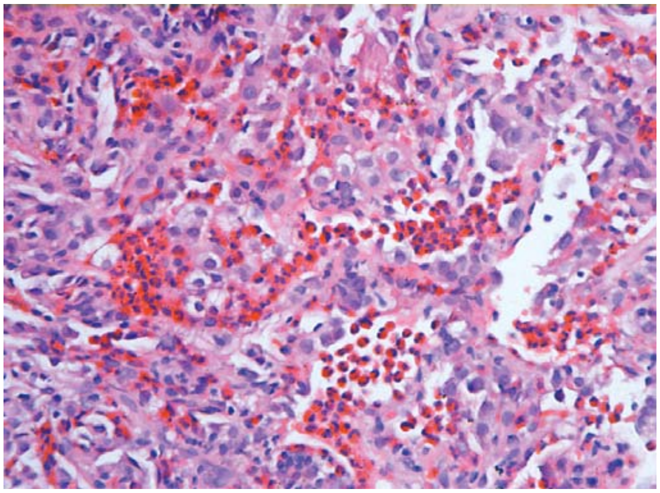

Fig. 97.3: Extensive eosinophilic infiltration of tissues on histopathological examination

TABLE 97.5: Laboratory diagnosis of myeloproliferative and lymphoproliferative variants of HES

Myeloproliferative variant	*Lymphoproliferative variant*
Definitive evidence: • FIP1L1-PDGFRA fusion • Eosinophil clonality	Definitive evidence • Phenotypically aberrent aberrant T Cells • TCR rearrangement • Increased eosinophilopoietic cytokines
Supportive evidence: ≥4 of • Increased serum tryptase • Increased serum B_{12} • Splenomegaly • Anemia, thrombocytopenia • Increased circulating myeloid precursors • Dysplastic eosinophils • Myelofibrosis • Increased spindle shaped mast cells in BM	Supportive evidence • Increased serum TARC • Increased serum IgE • Predominantly cutaneous manifestations • H/O atopy • Steroid responsive

The differential diagnosis includes the different eosinophilic disorders like CEP, CSS, acute eosinophilic pneumonia, tropical pulmonary eosinophilia, fungal infections and parasitic infestations, etc. Different laboratory criteria are used for the differential diagnosis of lymphoproliferative and myeloproliferative variants (Table 97.5).

Treatment

Treatment depends upon the presence of end-organ dysfunction. In clonal and idiopathic hypereosinophilia, the aim of the treatment is to limit/reverse end-organ damage and provide symptomatic improvement. In asymptomatic patients without any evidence of end-organ damage, a careful follow-up and assessment of any end-organ damage may be a prudent policy.

Asymptomatic peripheral eosinophilia can be followed up every three to six months without any treatment. The first line of therapy consists of steroids, which are given orally. Prednisone, in a dose of 1 mg/kg/day for one to two months is followed by a slow taper to a maintenance dose, which can be continued for one year or longer as required. In refractory cases, treatment with hydroxyurea, vincristine, chlorambucil, cyclosporine or interferon-α, can be tried.[34,44] The anti-IL5 antibody, mepolizumab has also been used in patients with high IL5 levels.[45,46]

Even though steroids had been the mainstay of treatment in the past, it is now realized that patients with myeloproliferative variant do not respond well to steroids and in case of FIP1L1-PDGFRA positive patients, use of tyrosine-kinase inhibitors such as imatinib[47] and dasatinib results in a gratifying response. Initial dose for a rapid cytogenetic response should be 400 mg/day with a lower maintenance dose. Whereas this variant is associated with exquisite sensitivity to imatinib even at a dose of 100 mg/day, other variants may require higher dosage and have variable response. Steroids should be added to imatinib in patients with evidence of myocarditis on echocardiography, electrocardiography or biochemical parameters (elevated serum troponin). The anti-CD 52 antibody, alemtuzumab has been tried in refractory cases especially those of lymphoproliferative variant.[48,49] There are several reports of successful treatment using hematopoietic stem cell transplant in refractory cases.[50-56]

The causes of mortality in HES include refractory congestive cardiac failure, renal failure, hepatic failure, venous thromboembolism, gut perforation and infections. However, proper treatment leads to a mean survival of greater than 10 years.

Other Eosinophilic Lung Diseases

Langerhans Cell Granulomatosis

Histiocytosis X consists of three closely related disorders, occurring at different ages: Langerhans cell histiocytosis, Letterer-Siwe disease and Hand-Schüller-Christian disease.[57] Primary pulmonary histiocytosis X, earlier known as eosinophilic granuloma of the lung, is almost exclusively found in smokers. The male to female ratio is 1:1; patients in the third and fourth decades of life are commonly affected.

It presents with cough, dyspnea, hemoptysis, chest pain, fever, wheezing, weight loss and recurrent, often bilateral pneumothorax. Patients also develop diabetes insipidus and bony disease. Chest X-ray shows involvement of the upper and middle zones with sparing of the costophrenic angles, reticulonodular changes, cystic lesions and bullae that may rupture to cause recurrent pneumothorax. Pulmonary function tests (PFTs) may show either a restrictive or an obstructive defect.

Histopathologically, a granulomatous infiltrate of histiocytes, eosinophils and other cells can be seen. The histiocyte is a large cell with an indented nucleus that has Birbeck granules on electron microscopy. S-100 antibody can also be found (Figs 97.3 and 97.4).

Treatment is based on the severity of the disease. Smoking should be stopped and patient treated with corticosteroids. Vincristine, cyclophosphamide and fludarabine have also been used. The mortality rate is less than 5% in adults.

Sarcoidosis

It is a multisystem disorder with pulmonary involvement in the majority of cases (Chapter 96). Patients may present with fever, weight loss, mediastinal lymphadenopathy and lung infiltrates. Histopathological examination reveals noncaseating epithelioid granulomas. Tuberculosis is a close differential diagnosis, especially in the Indian subcontinent. The incidence of eosinophilia in sarcoidosis ranges from 10 to 67%.[58]

Neoplastic Disorders

Eosinophilia may occur in association with several neoplastic conditions, both with hematological malignancies and solid organ tumors. The presence of eosinophilia may or may not be an adverse prognostic sign, depending upon the underlying disorder.

Hematological disorders associated with eosinophilia include systemic mastocytosis (in approximately 20%),[59,60] nodular sclerosing Hodgkin's disease (15%),[61] B-cell non-Hodgkin's disease,[61] T-cell leukemia and Sézary syndrome.[62] Of course, eosinophilic leukemia is a well known variant of acute myelomonocytic leukemia (M4).[63]

Solid organ malignancies include large cell cancer of the lung, squamous cell carcinomas of cervix, skin, nasopharynx, bladder transitional cell carcinoma, etc.[64-68]

Tropical Pulmonary Eosinophilia

It is an important cause of marked eosinophilia, hence an important differential diagnosis (Chapter 62).

Infections

Eosinophilia occurs with a variety of infectious agents, which include bacterial, fungal and parasitic diseases. An undulating pattern of eosinophilia that corresponds to disease activity has been noted in tuberculosis.[69] It has been shown that eosinophilia correlates with a good prognosis while eosinopenia was noted in fulminant or miliary disease.

Chronic brucellosis is also known to be associated with eosinophilia.[70] The fungal infection most commonly associated with eosinophilia is coccidiomycosis in which it occurs as a hypersensitivity phenomenon.[71,72] Other fungal infections include rare case reports of eosinophilia associated with *Histoplasma capsulatum* and cryptococcosis.

Drug- and Toxin-Induced Pulmonary Eosinophilia

A variety of drugs and toxins are associated with eosinophilic lung disease (Table 97.6).[73] The signs and symptoms of disease may manifest anywhere from a few minutes after exposure to weeks afterwards. One of the more common drugs to be implicated is nitrofurantoin, which causes acute, subacute and chronic reactions (Chapter 114).[74]

Symptoms, as already detailed, occur variably after exposure to the drug. These include low-grade fever, cough and dyspnea with or without wheezing. Examination might show wheezing and crackles and the peripheral blood will show eosinophilia. Chest X-ray may reveal diffuse or patchy pulmonary infiltrates; CT scans show bilateral consolidation and ground-glass opacification, both of which may be peripheral. Pulmonary function tests may either be absolutely normal, or show a reduced DLCO or a mild restrictive defect.

The syndrome usually disappears after discontinuation of the responsible drug. Corticosteroids are not universally beneficial, though their use may hasten recovery, especially in sick patients.

APPROACH TO DIAGNOSIS AND CONCLUSION

It is apparent that eosinophilic lung diseases are heterogeneous disorders that require a meticulous history taking, painstaking examination and judicious use of investigations to reach a definite diagnosis. A simplified algorithm that may be useful is given in Fig. 97.4. It is important to reach a diagnosis because these illnesses have different course and complications and thus involve important treatment decisions.

TABLE 97.6: Drugs causing eosinophilic lung disease

1. **Antimicrobials**
    - Para-amino salicylic acid
    - Nitrofurantoin
    - Penicillin
    - Tetracycline
    - Streptomycin
    - Isoniazid
    - Sulfonamides
    - Tetracycline
    - Minocycline
    - Dapsone + pyrimethamine
2. **Antineoplastic and immunosuppressives**
    - Bleomycin
    - Methotrexate
    - Melphalan
    - Gold salts
    - Azathioprine
    - Penicillamine
    - Beclomethasone
3. **Nonsteroidal anti-inflammatory drugs (NSAIDs):**
    - Aspirin
    - Naproxen
    - Piroxicam
    - Nimesulide
    - Phenylbutazone
4. **Cardiovascular and antidiabetics:**
    - Amiodarone
    - Hydralazine
    - Thiazides
    - Clofibrate
    - Sulfonylureas
5. **Miscellaneous**
    - Carbamazepine
    - Phenytoin
    - Dantrolene
    - Methylphenidate
    - Imipramine
    - Cocaine or heroin exposure
    - Iodinated contrast media
    - L-tryptophan.

Infiltrative and Deposition Diseases

Pralay Sarkar, Arunabh Talwar

INTRODUCTION

There are several different diseases characterized by the deposition of abnormal materials, either endogenous or exogenous, in the pulmonary parenchyma or in other areas of the respiratory system. Although rare, they frequently pose problems in the differential diagnosis of common clinical conditions, which present with similar respiratory or other clinical manifestations. Not infrequently, they are responsible for long delays in establishing the diagnoses.

PULMONARY AMYLOIDOSIS

Introduction

Amyloidosis is a group of disorders characterized by the extracellular tissue deposition of fibrils as beta-pleated sheets, disrupting organ function. These deposits are composed of low molecular weight subunits (most in the molecular weight range of 5 to 25 kD) of a variety of proteins, which circulate as the constituents of plasma. Current nomenclature of amyloid is based on the precursor proteins.[1] The pattern of organ involvement often depends on the nature of the precursor protein, many of which are associated with specific disease entities[1] (Table 98.1). Most common types of amyloidosis associated with pulmonary involvement are either AL or AA amyloidosis (see below). Amyloidosis has association with a wide range of systemic diseases, most commonly plasma cell dyscrasias, chronic infections or inflammatory conditions (Table 98.2).

Pulmonary Involvement in Amyloidosis

The first case of amyloidosis confined to the lower respiratory tract was described by *Lesser* in 1857, based on an autopsy. Pulmonary involvement with amyloidosis can occur in one of the three circumstances (Table 98.3). The Mayo clinic experience, based on retrospective review of pathological specimens, remains one of the best descriptions of pulmonary involvement with amyloidosis.[2] In their 55 patients recorded over a period of 13 years, 35 (66%) had primary systemic amyloidosis (including 3 of 35 patients with multiple myeloma), while 30% had localized (primary) pulmonary involvement. In systemic amyloidosis, lung is rarely the predominant organ involved clinically.[3] Pathological involvement of lung, however, has been described as a rule in primary systemic amyloidosis with amyloid deposition noted at autopsy in over 90% of patients.[2,4,5] In secondary systemic amyloidosis, pulmonary involvement is reported to be low, is usually mild and takes a different pattern of deposition with prominent perivascular component; most of these patients have no respiratory symptoms attributable to amyloid deposition, and have normal chest radiograph.[4-6]

Amyloid deposition limited only to lungs, called primary (localized) pulmonary amyloidosis is diagnosed on the basis of following criteria:[7] a. positive immunohistochemical staining for k and λ light chains (AL amyloid) in a respiratory tract biopsy *or* negative staining for serum AA protein, hereditary amyloid of transthyretin-type (TTR); b. no evidence of plasma cell dyscrasia on bone marrow biopsy; c. negative urine or

TABLE 98.1: Major types of amyloidosis[1]

Protein class	*Protein name*	*Amyloid type*	*Clinical presentation*	*Pulmonary involvement*
Immunoglobulin gene superfamily	Ig light chain/Ig heavy chains (IgL/IgH)	AL/AH	Primary systemic amyloidosis; Amyloidosis associated with multiple myeloma and other monoclonal gammopathies	Yes, almost universal in autopsy studies
	Beta-2 microglobulin	A β2m	Dialysis amyloidosis	Yes
High-density apolipoproteins	(Apo) serum AA	AA	Amyloid complicating chronic infections or inflammatory diseases; some heredofamilial periodic fever syndromes, such as familial Mediterranean fever (FMF)	Less frequent, usually not significant clinically
Transport protein	Transthyretin (TTR; prealbumin)	ATTR	Hereditary neuropathic and/or cardiopathic amyloids; senile systemic amyloidosis	

TABLE 98.2: Different diseases and other conditions associated with (pulmonary) amyloidosis

Blood dyscrasias/Hematologic malignancies/Lymphoproliferative disorders

Multiple myeloma
Waldenström's macroglobulinemia
Non-Hodgkin's lymphoma (NHL)
MALT lymphoma of the lung

Connective tissue disorders

Rheumatoid arthritis
Systemic lupus erythematosus
Mixed connective tissue disorder
Primary Sjögren's syndrome

Other conditions

End-stage renal disease on hemodialysis
Asbestos inhalation
Liver transplantation
Bone marrow transplant
Sarcoidosis
Familial Mediterranean fever
Dystrophic epidermolysis bullosa

TABLE 98.3: Pulmonary amyloidosis

- Pulmonary involvement in systemic amyloidosis: Lung involvement as a part of multisystem involvement
    - Primary systemic amyloidosis: Pulmonary involvement almost universal
    - Secondary systemic amyloidosis: Pulmonary involvement is infrequent and mild
- Organ specific involvement of lung without any evidence of systemic amyloidosis: Primary (localized) pulmonary amyloidosis
- Organ specific pulmonary amyloidosis in association with other pulmonary disorders
    - Sarcoidosis
    - Sjögren's syndrome with multiple pulmonary cysts
    - Pulmonary neoplasms: Anaplastic tumor or carcinoid
    - Lymphocytic interstitial pneumonia
    - Pulmonary mucosa-associated lymphoid tissue (MALT) lymphoma

serum studies for paraproteins; d. characteristic distribution and pattern of localized respiratory tract disease on computed tomography (CT) scan; e. no extrapulmonary involvement on serum amyloid P component (SAP) scan; and f. negative echocardiogram. Amyloid can involve both the upper and the lower respiratory tracts in a variety of pathological patterns (Table 98.4).

Pathogenesis

The pathogenesis of localized pulmonary amyloidosis remains obscure. In case of immunoglobulin light-chain (AL) amyloid, deposition is postulated to occur following a localized monoclonal proliferation of lymphoplasmacytic cells in pulmonary parenchyma; however, monoclonal plasma cell proliferation is not found in

TABLE 98.4: Clinicopathological patterns of respiratory system involvement in amyloidosis

- Tracheobronchial amyloidosis
- Solitary pulmonary nodule
- Nodular amyloidosis
- Alveolar septal amyloidosis
- Pulmonary vascular amyloidosis

- Other thoracic or respiratory tract amyloidosis
  - Laryngeal
  - Intrathoracic lymphadenopathy
  - Mediastinal mass
  - Mediastinal hemorrhage
  - Pulmonary hypertension
  - Diaphragmatic paralysis

many such cases. Another theory postulates that the circulating amyloid precursor molecule is deposited in the lung as a result of increased regional vascular permeability, possibly due to local inflammation. Polyclonal plasma cell infiltrates, often found in association with the amyloid deposits in the lung, are considered to reflect residual inflammation or a reactive inflammatory reaction to amyloid deposition. It is also possible that lung being in direct contact with environmental antigens, an abnormality of the local secretory immune system may contribute to amyloid deposition. Low pH and interaction with glycoaminoglycan help in deposition of amyloid.[8]

Clinical Types, Presentation and Diagnosis

1. Tracheobronchial Amyloidosis

Tracheobronchial amyloidosis is a rare disease. Here amyloid deposition typically occurs in the submucosa of trachea and main bronchi, sometimes extending to the level of segmental bronchi. Tracheobronchial amyloidosis usually occurs as an isolated airway involvement without that of lung parenchyma or other organs. Tracheobronchial involvement may be focal or diffuse, the later being more common.[9,10] Tracheobronchial amyloidosis has been associated with tracheobronchopathia osteochondroplastica though the causative relationship of these two rare conditions remains debatable.

Clinical presentation: Most cases have been reported in the fifth and sixth decades of life.[9] The presentation is predictable from the site of involvement: cough, dyspnea, recurrent hemoptysis and wheezing are common symptoms. Significant narrowing of airway can happen, leading to consequences like atelectasis and recurrent pneumonia.[11] Rarely, tracheobronchomalacia due to amyloidosis of the trachea has been reported.[12]

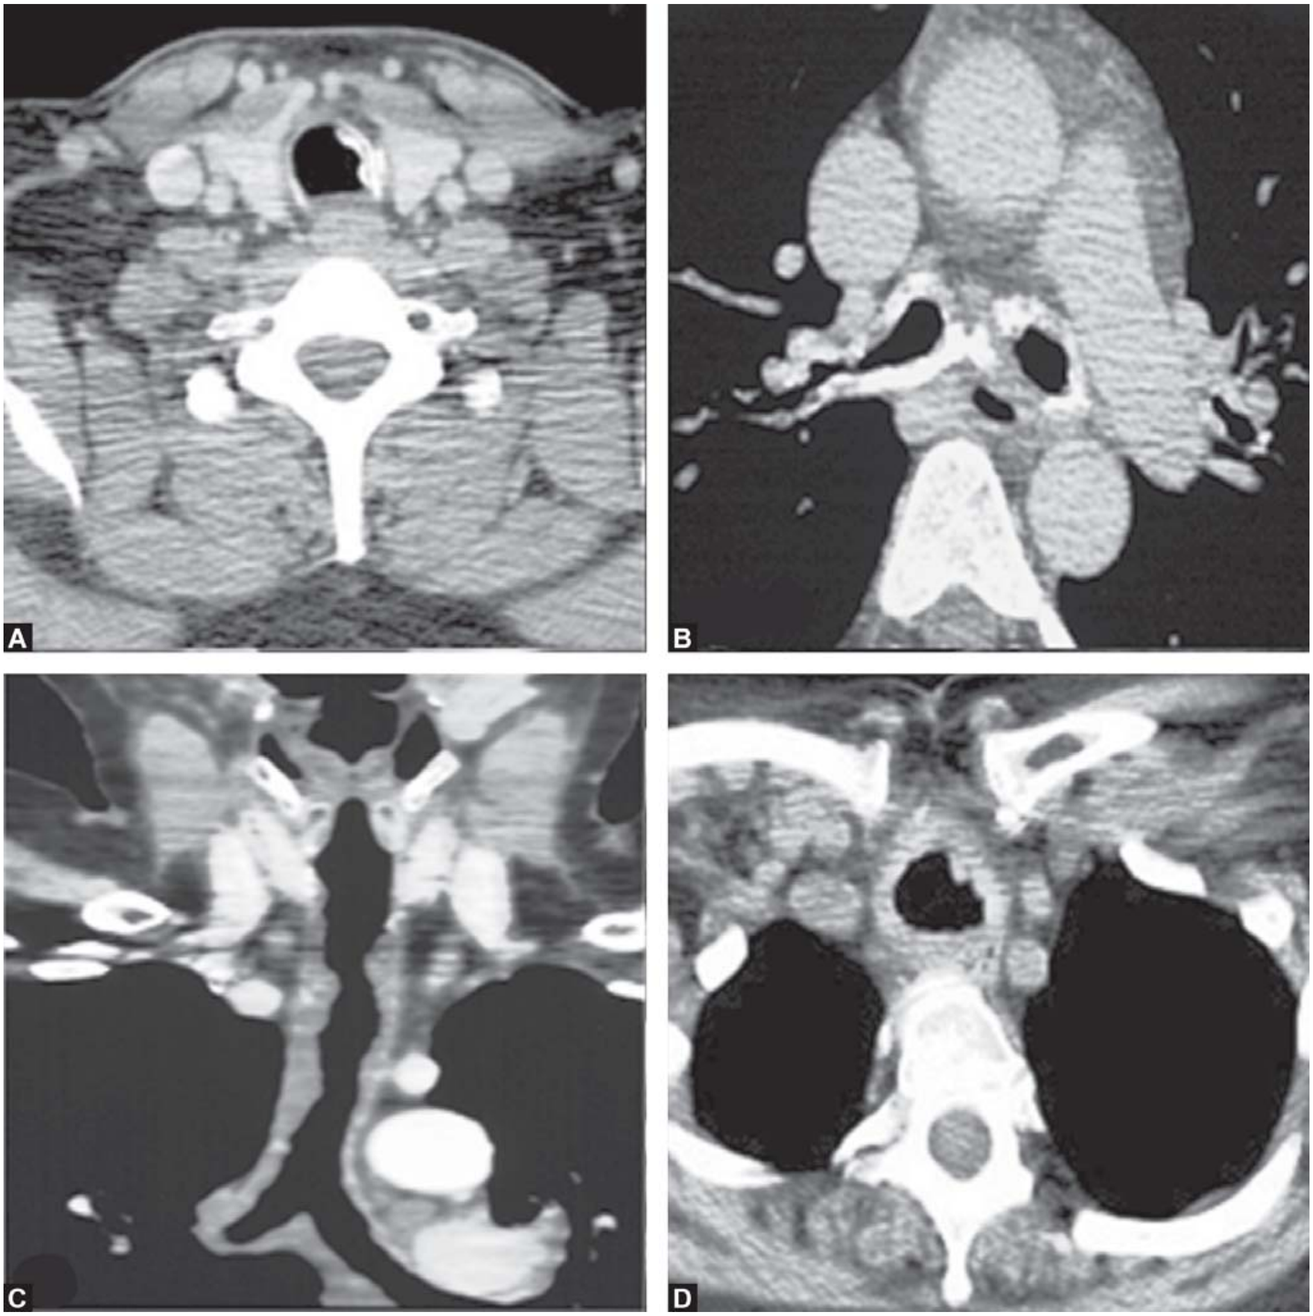
Diagnosis: The nonspecific clinical presentation of tracheobronchial amyloidosis can lead to delay in diagnosis. Often the disease is misdiagnosed as (refractory) asthma or chronic bronchitis for a long period of time.[11] Lung function tests may show evidence of large airway obstruction. Chest X-ray (CXR) and CT may show focal or diffuse thickening of the airway wall (Figs 98.1A and B), nodular and irregular narrowing of airway lumen (Fig. 98.1C), and localized nodule in the airway lumen (Fig. 98.1D). CXR can also show the consequences of airway obstruction like pneumonia, distal atelectasis or hyperinflation of lung distal to the obstruction.[10,13] CXR sometimes may be normal adding initial difficulty to the diagnosis.[14]

Bronchoscopy shows different endoscopic patterns: submucosal plaques, pseudotumor appearance, circumferential wall thickening; these are believed to represent different stages of the same process of amyloid deposition.[15] The deposits on bronchoscopy typically appear yellowish, often shiny and pale, with indistinct outline of cartilaginous rings and intact overlying mucosa (Fig. 98.2).[14] On macroscopic examination of the affected tissue, the amyloid deposits appear as irregular nodular masses or as diffuse sheets. Microscopically, the nodular masses or diffuse sheets are made of pink, amorphous, acellular material on hematoxylin and eosin (H and E) stain (hyaline deposits) (Fig. 98.3). Congo red staining shows apple-green birefringence under polarized light. Macrophages, foreign-body giant cells, microscopic calcifications, osseous metaplasia can be seen.[9] Submucosal blood vessels may also show amyloid deposition. Localized tracheobronchial amyloidosis is usually AL type, but AA type amyloid has been found in rare cases.[16]

2. Nodular Pulmonary Amyloidosis

In this type of pulmonary amyloidosis, nodular deposits of amyloid occur in pulmonary parenchyma, usually bilaterally at multiple sites. Nodular pulmonary amyloidosis is usually not associated with systemic amyloidosis. Presentation as a single nodular lesion/mass (amyloidoma) may also occur.[17]

Diagnosis: Average age of presentation is in the sixth decade of life. Nodular amyloid is commonly asymptomatic, often found incidentally on CXR or at autopsy.[9] Symptoms arise when a large mass produces its mechanical effects: patients present with cough and progressive dyspnea. Significant weight loss has also



Figs 98.1A to D: Tracheobronchial amyloidosis: A. Localized thickening of upper trachea; B. Diffuse thickening of tracheal wall at the level of carina; C. Sagittal section of trachea showing irregular narrowing of airway; D. Localized amyloid nodule in the airway lumen
(*Courtesy:* Dr Rakesh Shah, Consultant Radiologist, North Shore University Hospital, Manhasset, NY, USA [Figs 98.1A to C]
Dr Subha Ghosh, Consultant Radiologist, Ohio State University, Columbus, Ohio, USA [Fig. 98.1D])

been reported.[18] CXR and CT of the thorax show single or multiple pulmonary nodular opacities/masses of soft tissue density. These masses have irregular contour and are distributed diffusely, bilaterally and often asymmetrically.[18] Distribution of nodules may show lower lobe and subpleural preponderance. The size of most nodules ranges from 0.4 to 5 cm; an average nodule is ~3 cm in size and size up to 15 cm has been reported

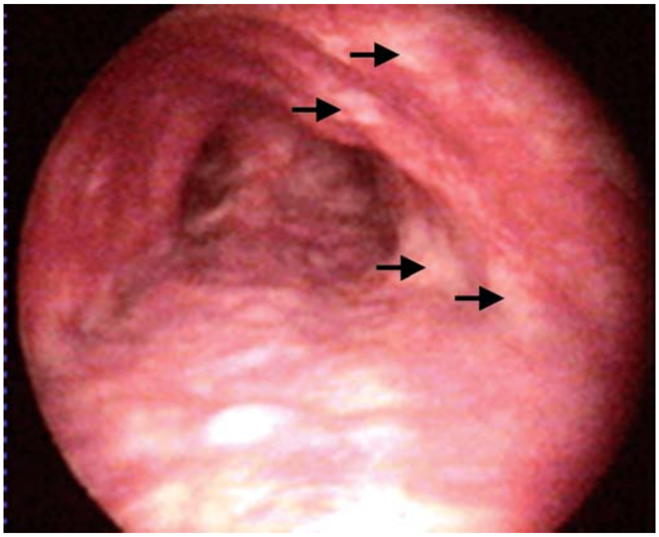


Fig. 98.2: Bronchoscopic view of tracheobronchial amyloidosis showing multiple yellowish, shiny submucosal deposits (marked with arrow)

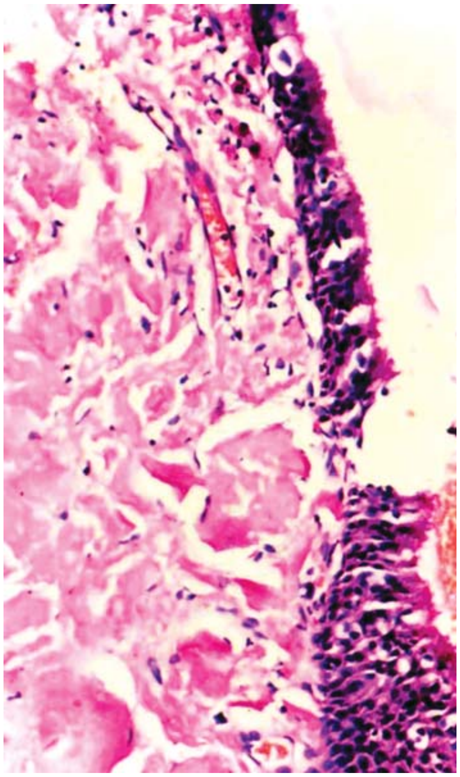

Fig. 98.3: Light microscopic appearance of a bronchoscopic biopsy specimen in a case of tracheobronchial amyloidosis. Diffuse sheets of pink, amorphous, acellular material are seen (hematoxylin and eosin [H and E] stain, 100X)
(*Courtesy:* Dr Ritesh Aggarwal, Assistant Professor, Department of Pulmonary Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India)

reported.[9,19] A solitary amyloidoma can grow unusually big with extension into the surrounding tissues[20] (Fig. 98.4). The nodular deposits may contain areas of calcification, may rarely cavitate.[21,22] Calcification is often subtle, apparent only on CT scan and can be the only clue to the diagnosis.

Nodular pulmonary amyloidosis has close radiological resemblance with primary/metastatic lung cancer. Therefore, biopsy is required to reach a diagnosis. Image-guided transthoracic fine needle aspiration (FNA) biopsy can be attempted, but the firm-to-hard consistency of deposits may cause difficulty in obtaining an adequate sample.[23] Bronchoscopic tissue sampling, including transbronchial lung biopsy, can give diagnosis in some cases.[2] Occasional report of accurate diagnosis with CT-guided bronchoscopic sampling can also be found.[24] However, serious adverse consequences have been reported in some cases following transbronchial biopsy, including reports of fatal pulmonary hemorrhage and arterial air embolism.[2,25] Open lung biopsy by thoracotomy or video-assisted thoracoscopy should often be the preferred approach for safe and adequate tissue sampling.

In pathological specimens, nodular amyloid deposits appear as irregular masses of eosinophilic amorphous material. Some nodules can have areas of ossification and/or calcification. Small arteries or veins adjacent to or within the lesions may contain amyloid. Clusters of plasma cells and giant cells are seen adjacent to or within the amyloid deposits (more frequently in the nodular parenchymal than in the tracheobronchial variant). A histological picture consistent with interstitial pneumonitis or granulomatous

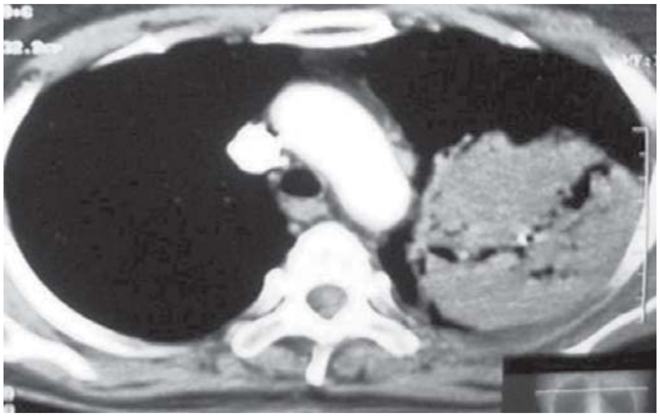

Fig. 98.4: Large solitary mass of amyloid deposit in the pulmonary parenchyma
(*Courtesy:* Dr Ritesh Aggarwal, Assistant Professor, Department of Pulmonary Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India)

pneumonitis can be found in a small number of cases.[9] Immunohistochemistry usually reveals AL amyloid; amyloid composed predominantly of beta 2-microglobulin has also been described.[23]

Differential diagnoses include primary and secondary neoplasms and granulomatous disorders.[26] In cases of solitary nodule/mass, careful sectioning of pathological specimen is necessary to rule out any neoplastic process as amyloid deposition has been described in association with primary lung tumor.[27,28] Amyloid deposits are usually fluorodeoxyglucose positron emission tomography (FDG-PET) negative, a point which may be useful in diagnosis; false positive results are however known adding difficulty to the diagnosis.[29,30]

3. Diffuse Alveolar Septal Amyloidosis

In this pathological pattern of pulmonary involvement, the microscopic deposits of amyloid occur diffusely within the alveolar septae and the interstitial tissue. Interstitial/alveolar septal pulmonary amyloidosis is usually seen as a part of the systemic amyloidosis.[2] It is rare for primary/localized pulmonary amyloidosis to show a diffuse interstitial pattern and till 2009, only 11 such well documented cases have been reported in the literature.[31]

Clinical presentation: The patient may be asymptomatic or may present with progressive dyspnea. The severity of clinical symptoms depends on the extent the gas exchange zones, namely alveolar septae and capillaries are involved. Majority of these patients have significant cardiac involvement complicating the picture in many of these patients. Diffuse alveolar hemorrhage leading to fatality has been reported with this form of amyloidosis.[32]

Diagnosis: Pulmonary function tests reveal a restrictive physiology with impaired gas exchange that parallels with the extent and pattern of interstitial amyloid deposition. A high-resolution computed tomography (HRCT) scan of the thorax reveals interlobular septal thickening or irregular lines that frequently have a predominant basilar and peripheral distribution.[33] Small (2-4 mm in diameter), well defined nodules and confluent areas of consolidations can also be seen. Some nodules may show calcifications and some of the areas of consolidation may contain punctate foci of calcification, a subtle clue to the diagnosis. Radiological changes often predominate in the subpleural regions. Associated pleural effusion, mediastinal and hilar lymphadenopathy may be seen. Rarely, CT scan might reveal multiple cysts of variable size with surrounding high-density areas.[21,34-36]

Histopathologically, variable amount of amyloid deposition is found in the pulmonary interstitium: alveolar septa, capillaries, as well as in the wall of bronchioles, arterioles, venules and in lymphatic vessels.[37,38] Interstitial/septal amyloid deposit may be present as diffuse and uniform or as multiple small interstitial nodules.[9] Correlating with radiological findings, thickening of interlobular septa with amyloid deposition can be shown in histological specimens. Extensive deposits are also found beneath the visceral pleura. Areas of calcification and ossification are found within the affected areas.[35]

4. Pleural Disease

Pleural effusion is a rare manifestation of systemic amyloidosis. Significantly large, persistent pleural effusions have been reported in 6% cases in a large series of AL amyloidosis; less significant effusions are seen in ~10 to 15% cases.[38] Pleural effusions are not usually seen in secondary (AA) amyloidosis.[4,5] Cardiac involvement and congestive heart failure are common in AL amyloidosis. Pleural effusions may result from congestive heart failure; the pleural fluid in these cases is expected to be transudative in character. However, one-third of the persistent pleural effusions in primary amyloidosis are exudative, which cannot be explained by cardiac involvement alone.[39] Large persistent effusions are the result of direct involvement of the parietal pleura.[40] Apart from being exudative, cellular characteristics of the effusions do not have any distinctive feature to point to the diagnosis. Pleural infiltration by amyloid can be demonstrated by thoracoscopy and can be proven by pleural biopsy.[41-43] AL amyloidosis patients sometimes develop nephrotic syndrome and hypothyroidism, secondary to infiltration of the kidney and the thyroid gland respectively. Both nephrotic syndrome and hypothyroidism may contribute to pleural effusions in these patients, though their contribution remains debated.[39] Lymphatic infiltration with amyloid can lead to chylous effusion.[44]

5. Other Manifestations of Respiratory System Amyloidosis

Pulmonary hypertension has been known to develop in systemic amyloidosis with or without the presence of parenchymal lung involvement.[31,45,46] Deposition of amyloid in the pulmonary vasculature is responsible for this uncommon development.[47] Pulmonary hypertension has been described in primary systemic AL amyloidosis, as well as in AA amyloidosis related to familial Mediterranean fever (FMF).

Diffuse pulmonary hemorrhage has been described as a first manifestation of pulmonary amyloidosis. Amyloid angiopathy, involving small- and medium-sized pulmonary arteries, may cause ***pulmonary arterial dissection***, presenting with recurrent hemoptysis.[48] Rupture of an amyloid-involved vessel may cause ***pulmonary hematoma***.[49] Amyloid deposition in vessel wall may cause fragility and lead to the formation of ***arteriovenous fistula***.[50]

Involvement of nasopharynx, paranasal sinuses: Leads to chronic infections and contribute to obstructive sleep apnea.

Laryngeal amyloidosis: Laryngeal involvement causes long-standing hoarseness of voice. It may also cause airway obstruction. Amyloidosis localized to the larynx has been rarely reported to cause fatal upper respiratory tract hemorrhage.[51]

Mediastinal lymphadenopathy: Mediastinal, as well as unilateral or bilateral hilar lymphadenopathy can be seen in amyloidosis. Lymph node involvement is usually a part of systemic amyloidosis.[21] It is an unusual manifestation in localized pulmonary amyloidosis though hilar or mediastinal lymphadenopathy has been described in conjunction with tracheobronchial amyloidosis. Very rarely, mediastinal or hilar lymphadenopathy in the absence of pulmonary involvement, has been reported as the only manifestation of localized amyloidosis.[52] Lymph nodes involved in amyloidosis present homogeneous low attenuation and faint or stippled calcification.

Diaphragmatic paralysis: Diaphragm dysfunction has been reported in systemic amyloidosis as a result of infiltrative myopathy.[53,54] Alternatively, diaphragm paralysis may result from amyloid-induced mononeuritis multiplex.[55]

Treatment

A variety of management strategies, such as observation in selected cases, intermittent bronchoscopic intervention, surgical resection and external beam radiation are used in laryngotracheobronchial amyloidosis.[15] In a given case, the choice of treatment strategy depends on the extent of involvement, the size, location and appearance of the lesions, the functional consequences of amyloid deposition and the availability of expertise in a particular institution. Bronchoscopic procedures include the mechanical debulking/resection with/without dilatation, transmucosal Nd:YAG laser treatment (for pseudotumoral mass or circumferential thickening), carbon dioxide laser ablation (for submucosal lesions) and stent placement (after establishing patency of airway lumen).[15,56] Majority of the cases can be managed by bronchoscopic procedures. Open neck surgical approach for the management of laryngotracheal amyloidosis is rarely necessary.[57] External beam radiation has been successfully used in the treatment with functional improvement, as well as the regression of lesions.[58]

In patients with secondary systemic amyloidosis, treatment of the underlying inflammatory or chronic condition is recommended. The response to tumor necrosis factor α blockade has been described in patients with rheumatic diseases who developed systemic AA amyloidosis.[59-61] Sustained improvement in proteinuria and renal function has been consistently reported though no information is available about the efficacy of these agents for the pulmonary involvement. Patients with systemic amyloidosis, who have an underlying hematological condition like multiple myeloma, Waldenström's macroglobulinemia or other monoclonal gammopathies, need treatment for the underlying condition.

Various treatment options are available for primary systemic amyloidosis (AL amyloidosis) (Table 98.5). For decades, alkylating agents have been the mainstay of treatment, often in combination with high-dose dexamethasone (Table 98.5). Intermediate dose chemotherapy regimens, adapted from chemotherapy of multiple myeloma, have also been used with success. As the general prognosis of primary systemic amyloidosis remains poor, hematopoietic stem-cell transplantation (HSCT) has been advocated as one approach to achieve survival better than chemotherapy.[62,63] Caution should be exercised while interpreting the available data, particularly while choosing HSCT over chemotherapy. Patients who are considered eligible for HSCT comprise a good-risk population. This group of patients do relatively well with chemotherapy (median survival 42 months), substantially better than the expected median survival of 18 months for all patients with AL amyloidosis on chemotherapy.[64] Using a variety of chemotherapy or cytotoxic regimens, (adapted from multiple myeloma therapy) (Table 98.5), result comparable to HSCT (survival of ~ 60% after a median follow-up of > 20 months) were found.[65-67] Chemotherapy remains the first line management for primary systemic amyloidosis. In selected patients or in patients who fail to respond to chemotherapy, HSCT is a choice. Specific clinical or radiological response of pulmonary lesions to any form of treatment has scarcely been reported.[68] The optimal approach for treating isolated

TABLE 98.5: Treatment of primary systemic amyloidosis

Standard dose alkylating agents with dexamethasone
Monthly courses of oral melphalan (10 mg per square meter of body-surface area on days 1 to 4) plus high-dose oral dexamethasone (40 mg per day on days 1 to 4): for up to 18 treatment courses (12 courses if complete remission has been achieved).
High-dose melphalan with autologous hematopoietic stem cell transplantation (HSCT)
Melphalan, 200 mg per square meter given intravenously on day 0, and stem cells were infused on day 2.
Intermediate dose chemotherapy regimens (regimens adapted from multiple myeloma treatment)
Vincristine, adriamycin and dexamethasone (VAD) Cyclophosphamide, vincristine, adriamycin and methylprednisolone (C-VAMP) Intermediate-dose melphalan (IDM)

pulmonary interstitial amyloidosis is undefined. Colchicine has been tried. Symptomatic improvement with prednisone and azathioprine has been reported.[31]

Management of heart failure is the mainstay of treatment in the cases where the effusions result from heart failure. Refractory pleural effusions, secondary to direct amyloid involvement of pleura, pose a difficult therapeutic challenge. These patients should be managed with diuretic therapy and intermittent thoracentesis. When thoracentesis is required weekly or more frequently, measures of a more sustained nature should be adopted to prevent accumulation of pleural fluid. These measures include one of the following: tube thoracostomy and pleurodesis, video-assisted thoracoscopy with talc insufflations for pleurodesis, or placement of a drainage system that can be kept in place for long time and be intermittently drained at home (e.g. *Pleurx tube*). Recently, four patients reported with AL amyloidosis who presented with bilateral pleural effusions, refractory to diuretic therapy were treated with bevacizumab, an antivascular endothelial growth factor (VEGF) antibody.[69] Three of the four patients had improvement in their pleural effusions. Further studies are required to define the role of this novel agent in the management of amyloidosis-related pleural effusion.

Prognosis

The prognosis of pulmonary amyloidosis depends on the type and extent of lung involvement, as well as on the involvement of other major organs. In tracheobronchial amyloidosis, the prognosis is not always benign. Some patients die of respiratory failure or recurrent pneumonia secondary to bronchial obstruction.[9] Severe hemoptysis also remains an important complication. Recurrence of isolated endobronchial masses after resection is rare. Nodular pulmonary amyloidosis typically runs a benign course, generally has an excellent prognosis. Nodules grow slowly over years without any regression. Follow-up of cases over 6–20 years has been reported.[70-72] Occasionally, patients may develop large lesions producing space-occupying effects.

Long-term prognosis of patients with primary systemic amyloidosis remains poor. A median survival of 16 months was reported in the Mayo clinic series.[2] Pulmonary involvement in itself contributes to death in a small proportion of cases.[4,37] Many of the patients with primary amyloidosis have other major organ involvement, notably cardiac and renal involvement, causing death. Overall, the presence of pulmonary amyloidosis in patients with primary systemic amyloidosis portends a poor outcome, whether the pulmonary component of the disease is directly related to death or is simply a marker of an otherwise advanced disease.[2] In the rare presentation of alveolo-septal form of localized pulmonary amyloidosis, the prognosis is generally poor with death occurring from progressive respiratory failure within two years.

LYSOSOMAL STORAGE DISORDERS

Lysosomal storage disorders (LSDs) are a diverse group of hereditary metabolic disorders caused by defects in lysosomal function. Most commonly, these disorders result from mutations in genes that encode catabolic enzymes (e.g. lysosomal hydrolases) involved in the degradation of macromolecules. Failure to degrade macromolecules causes accumulation of the same in the cells leading to cellular dysfunction and progressive clinical manifestations. More than 45 diseases have been described till date, most being inherited in an autosomal recessive manner[73] (Table 98.6).

The clinical expression of LSDs is variable. The age of onset, the severity of symptoms and the pattern of organ involvement can vary markedly within a single disorder type or subtype. Clinical manifestations differ according to the residual enzyme function, genetic and environmental factors. Many of these disorders, e.g. Gaucher, Tay-Sachs, Pompe, metachromatic leukodystrophy, and GM1 gangliosidosis have infantile, juvenile and adult forms. Many LSDs have upper and/or lower respiratory tract involvement. A detailed description of all the entities is beyond the scope of this chapter. Respiratory involvement can occur in various LSDs

TABLE 98.6: Classification of lysosomal storage disorders (by affected lysosomal function)

Nature of defective lysosomal function	*Prototype disorder*
Defective metabolism of glycosaminoglycans	Mucopolysaccharidosis (MPS) I–IX
Defective degradation of glycan portion of glycoproteins	Aspartylglucosaminuria, fucosidosis, mannosidosis, Schindler disease, sialidosis type I
Defective degradation of sphingolipid components	Fabry disease, Farber disease, Gaucher disease (types I–III) GM1- gangliosidosis, GM2-gangliosidoses (Tay-Sachs disease, Sandhoff disease, GM2 activator disease), Krabbe disease, metachromatic leukodystrophy, Niemann-Pick disease (type A or B).
Defective degradation of glycogen	Pompe disease
Defective degradation of polypeptides	Pycnodysostosis
Defective degradation or transport of cholesterol, cholesterol esters, or other complex lipids	Ceroid lipofuscinosis, cholesterol ester storage disease, Niemann-Pick disease type C, Wolman's disease
Multiple deficiencies of lysosomal enzymes Multiple sulfatase	Galactosialidosis
Transport and trafficking defects	Cystinosis, mucolipidosis IV, sialic acid storage disorder, chylomicron retention disease, Hermansky-Pudlak syndrome (several forms), Chédiak-Higashi syndrome
Unknown defects	Geleophysic dysplasia, Marinesco-Sjögren syndrome

(Table 98.7), some of whom have been also reported in adult patients.[74]

Anderson-Fabry Disease (AFD)

Introduction

Fabry disease is an X-linked recessive disease as a result of the deficiency of the lysosomal enzyme α-galactosidase A (α-gal A). It has no ethnic predilection and occurs in about 1:117,000 live births. AFD leads to progressive accumulation of glycosphingolipids, predominantly globotriaosylceramide (GL-3), in many body tissues over a period of years or decades. Clinical manifestations include renal failure in about 30% of patients and cerebrovascular accidents in about 25% of patients. A 15-year follow-up of patients from AFD clinical and genetic register (UK) reported the median age of 21.9 years at diagnosis and median cumulative survival of 50 years.[75] Obligate carrier females have also been reported to have clinical manifestations with a high frequency.[76]

Pulmonary Manifestations

Respiratory symptoms, consistent with airway involvement, are common in AFD patients.[77] In a cohort of 25 consecutive male patients with AFD, 36% complained of dyspnea and 24% had cough and/or wheezing.[78] Hemoptysis has also been reported. Interstitial involvement can also occur in AFD.[79] In line with symptoms of airway disease, chronic airflow obstruction is commonly reported on spirometry in AFD patients and is said to be more common in those who smoke.[78,80] Other investigators have reported features consistent with small airway disease, in more than half of both men and women with AFD.[77] A reduced diffusion capacity (DL_{CO}) is also a common finding.

The disease manifestations can be explained by the deposition of GL-3 within various compartments of the lower respiratory tract. The airflow obstruction is thought to be due to fixed airway narrowing secondary to deposition of GL-3 in airway epithelial cells as has been demonstrated by presence of inclusion bodies in bronchoscopic biopsy specimens.[80] Pathologic evidence for pulmonary parenchymal and vascular involvement have also been reported; hemoptysis may result from such direct vascular involvement or from angiectatic lesions in bronchi.

Diagnosis

Chest X-ray (CXR) can be normal in many patients. In keeping with the occurrence of airway disease, some of the patients have CXR changes suggestive of emphysema with or without bulla.[80] Pneumothorax can also occur. HRCT findings of lung involvement in AFD have been infrequently reported. In a recent report, HRCT demonstrated bilateral mosaic attenuation pattern. Regions of both abnormally lucent and dense lung parenchyma were present, reflecting a combination of ground-glass opacity and air trapping.[81]

TABLE 98.7: Respiratory manifestations of lysosomal storage disorders

Disease	*Upper respiratory tract involvement*	*Lower respiratory tract involvement*
(MPS I) Disease* (Hurler, Hurler-Scheie, Scheie syndromes)	Chronic rhinitis and rhinorrhea Enlarged tongue, tonsils, adenoids Obstructive sleep apnea	Narrowing of trachea Thickened vocal cords Reduced lung volumes Recurrent respiratory infections Respiratory failure common cause of death
(MPS II) Disease* (Hunter syndrome)	Recurrent ear infections Upper airway obstruction Progressive hearing loss	Pulmonary hypertension
(MPS III) Disease* (Sanfilippo syndrome)	Airway obstruction common cause of death	
(MPS IV) Disease* (Morquio syndrome)	Upper airway obstruction	Restricted chest wall movement leads to restrictive ventilator defect
(MPS VI) Disease* (Maroteaux-Lamy syndrome)	Enlarged tongue	
(MPS VII) Disease* (Sly syndrome)		Chronic inflammatory lung disease Recurrent respiratory infections
Aspartylglycosaminuria*		Kyphoscoliosis Recurrent respiratory infections
Fucosidosis – Type I	Macroglossia	Recurrent lung infections
Mannosidosis*		Recurrent respiratory infections
Pompe disease*	Macroglossia Sleep apnea	Recurrent lung infections
Acid Sphingomyelinase Deficiency (Niemann-Pick Disease Types A and B*)		Alveolar proteinosis
Fabry disease*		Chronic airflow obstruction
Farber disease	Vocal cord infiltration Hoarseness of voice	Recurrent respiratory infections
Gaucher disease – Type I* (Non-neuronopathic)		Pulmonary infiltration Kyphoscoliosis Pulmonary hypertension Restrictive lung disease Hypoxia secondary to liver disease
Gaucher disease – Type II (Acute infantile neuronopathic)	Laryngospasm Apneic episodes	
Gaucher disease – Type III (Chronic neuronopathic)*		Pulmonary infiltration Kyphoscoliosis Pulmonary hypertension Restrictive lung disease
GM1 gangliosidosis – Type I (Infantile Form)		Dorsolumbar kyphoscoliosis Recurrent pneumonia
GM1 gangliosidosis – Type II (Infantile Form)		Recurrent pneumonia
Sandhoff disease – Type I Mucolipidosis II (I-Cell disease)	Loss of swallowing Recurrent and persistent upper respiratory tract infections	Recurrent aspiration and pneumonia

*Survival into adulthood known
Disease entities marked in bold are discussed in details in the text

In a patient known to have AFD, characteristic manifestations point to pulmonary involvement and a tissue diagnosis may not be warranted. Where needed, diagnosis can be confirmed by demonstrating typical lamellar inclusion bodies in bronchial biopsy or brushings.[78,80] Cells present in induced sputum may also show inclusion bodies clinching the diagnosis.[82] Whether similar inclusion bodies are present in AFD patients without clinical lung involvement is not known. In a patient with the evidence of interstitial lung disease, lung biopsy may be indicated to rule out other diagnoses.

Management

Enzyme replacement therapy (ERT) for AFD has been available since 2003. Agalsidase beta (Fabrazyme®, Genzyme Corp.) and agalsidase alfa (Replagal®, Shire) are approved in USA, Europe and some other countries for treatment of AFD. ERT has been shown to improve symptoms, as well as renal and cardiac function.[83,84] ERT with agalsidase alfa 0.2 mg/kg every other week (EOW) or agalsidase beta 1.0 mg/kg EOW is the standard of treatment for this disease. Controlled data about the effect of ERT on progression of pulmonary function abnormalities are either scant or absent. Isolated case reports have shown significant improvement in radiological abnormalities and spirometry on ERT.[79] Renal involvement and neuropathy usually dominate the clinical picture in AFD; it can be anticipated that pulmonary involvement alone will rarely be the sole indication for ERT.

Gaucher Disease

Introduction

Gaucher disease is an autosomal recessive disorder as a result of the deficiency of the lysosomal enzyme glucocerebrosidase. It is the most prevalent lysosomal storage disorder. Gaucher disease leads to the accumulation of the lipid glucocerebroside within the lysosomes of the monocyte-macrophage system. Lipid-engorged cells (Gaucher cells) accumulate and cause organ dysfunction. Age of the onset of symptoms and their severity is variable. At an incidence of 1 in 40–60,000 live births, type I is the most common type. Type 1 is panethnic, but has higher frequency among Ashkenazi Jews. Type 1 Gaucher disease patients have normal life-expectancy and may present for the first time in adult life. Type III presents in late childhood/early adolescence and has more severe and rapidly progressive visceral disease. Type II disease rarely survives beyond the age of two years.

Pulmonary Manifestations

Pulmonary involvement has been reported in both type I and type III Gaucher disease, is more rare in type I and more severe in type III.[85] The frequency of symptomatic pulmonary involvement varies in literature from uncommon to common presentation.[86,87] Clinical picture is characterized by gradual onset and progression of dyspnea that in some cases culminates to respiratory failure and death. (Lung involvement is the second most common cause of death in type III Gaucher disease). Pulmonary involvement occurs due to infiltration by the Gaucher cells giving a pattern of interstitial lung disease (ILD). Pulmonary hypertension (PAH) has been reported in a significant proportion of adult patients and may be particularly severe, life-threatening in those who have had splenectomy for the management of the disease.[88] PAH in Gaucher disease can result from chronic hypoxemia secondary to interstitial disease, secondary to liver disease or due to long bone infarction and fracture with pulmonary emboli. Severe pulmonary hypertension can also occur in these patients primarily due to pulmonary capillary blockage by Gaucher cells, in absence of significant parenchymal involvement.[89] Other intrathoracic manifestations of Gaucher disease include: enlarged hilar and mediastinal lymph nodes that can sometimes lead to bronchial obstruction; increased incidence of pulmonary infections and hypoxemia due to intrapulmonary arterial-venous shunts in patients with severe hepatic disease. Large hepatosplenomegaly can cause the elevation of diaphragm and contribute to dyspnea.

Diagnosis

The chest radiograph may be abnormal with or without symptoms and show bilateral diffuse reticulonodular or miliary opacities. HRCT shows bilateral irregular interlobular, as well as intralobular septal thickening. The interstitial changes are more common in lower lung zones. Irregular costal margin and fissures indicate subpleural interstitial thickening. Additional ground glass opacities reflect interstitial and alveolar space disease.[90,91] Other reported HRCT findings include consolidation, alveolar opacities and bronchial wall thickening.[92] Additional findings also may include prominent pulmonary arteries as a result of the PAH. Osteopenia, cortical thinning and the widening of medullary spaces of clavicles and ribs can also be evident on the CXR.

Diagnosis is established by showing deficient glucocerebrosidase activity in peripheral blood leukocytes. In patients with respiratory involvement, bronchoalveolar lavage (BAL) reveals Gaucher cells;[93] these cells resemble macrophages with eccentric, small, oval nuclei and abundant cytoplasm with the characteristic "rumpled tissue paper" appearance. Gaucher cells stain strongly positive with periodic acid-Schiff stain. Electron microscopy reveals lysosomes containing the characteristic twisted tubular structures. Lung biopsy specimens also reveal similar cells. Lung biopsy may not be needed in known patients of Gaucher disease with typical respiratory manifestations.

Pathologic examination of the lungs reveal massive infiltration of alveolar septal walls, interstitial spaces in a lymphatic distribution, perivascular septal regions by Gaucher cells. Clumps of these cells also fill alveolar spaces and obliterate functional air exchanging tissue. In some cases, interstitial fibrosis may result. Alveolar hemorrhage and multiple pulmonary emboli are also seen in some cases.[94] In patients with PAH, apart from the characteristic arterial/arteriolar changes associated with PAH, the histological sections of lung disclose widespread plugging of the lumina of precapillary arterioles and alveolar capillaries by Gaucher cells.[89,95]

Management

Gaucher disease is the first LSD for which macrophage-targeted ERT was introduced in clinical practice (in 1991). Two modified forms of the enzyme β-glucocerebrosidase are in use: Alglucerase (Ceredase®, Genzyme Corporation, Cambridge, Massachusetts) and the recombinant analog imiglucerase (Cerezyme®, Genzyme Corporation). With imiglucerase, majority of the patients initiate therapy with doses ranging from 30 to 60 U/kg bodyweight given every fortnight. ERT is started in early childhood and has been found to be safe and effective in reducing organomegaly, skeletal complications and in improving hematological parameters.[96-98] Improvement in clinical signs of pulmonary disease, increased sense of well-being, stabilization of lung function, stabilization or improvement in chest radiological changes and improvement in lung pathology have been reported on ERT.[87,99] Lungs may be slow to respond to ERT in some patients and in some cases, pulmonary changes may be irreversible. In recent years, substrate reduction therapy (SRT) has come in practice in type I Gaucher disease; these medications (e.g. Miglustat, a small iminosugar), given orally, act to reduce substrate load either by inhibiting its synthesis or enhancing the residual activity of the endogenous mutant enzyme. The effect of SRT on lung disease is unknown.[100]

Niemann-Pick Disease

Introduction

Niemann-Pick disease (type A and B) is due to the deficiency of the enzyme acid sphingomyelinase (ASM). When ASM is deficient, sphingomyelin and cholesterol accumulate in lysosomes. Clinical manifestations are due to fat deposition in one or more organs. ASM deficiency can present along a continuum of severity. Severe ASM deficiency is associated with the type A phenotype (neuronopathic form presenting in infancy, death before 5 years of age). Non-neuronopathic ASM deficiency can present at any age and historically has been classified as Niemann-Pick disease type B phenotype. Niemann-Pick type C is a genetically distinct disorder resulting from defective intracellular trafficking of cholesterol and secondary accumulation of glycosphingolipids. Niemann-Pick disease is pan-ethnic though type A has higher frequency among Ashkenazi Jews; the incidence is 1 in 248,000 live births.

Pulmonary Manifestations

Pulmonary involvement has been reported in all types of Niemann-Pick disease.[101-103] Pulmonary symptoms result from alveolar lipoproteinosis. Pulmonary disease has been best described in type B disease. Respiratory manifestations may present at a variable age and rarely may be the initial presentation of this disease.[104,105] In the largest reported cohort of patients with type B disease, (59 patients, $\leq$ 6 years of age, 50% >18 years of age), shortness of breath and respiratory infections were common symptoms.[101] Various bleeding manifestations are common in this disease and hemoptysis and hemothorax have been reported. Cyanosis, clubbing, rales and wheezing may be present on physical examination. Pulmonary function tests are abnormal in vast majority of patients with type B disease, including those who have no symptoms.

Diagnosis

CXR shows reticulonodular opacities with the areas of ground glass haziness, often out of proportion to clinical manifestations.[104] HRCT shows variable combination of septal thickening and ground glass, diffuse and homogeneous.[102,105,106] The radiological evidence of interstitial lung disease has been reported to be present in nearly all patients with type B Niemann-Pick disease.[107]

Diagnosis of Niemann-Pick disease is based on the deficiency of ASM activity in peripheral leukocytes or in cultured skin fibroblasts/lymphocytes in the presence of characteristic clinical features. BAL shows numerous foamy macrophages (Niemann-Pick cells), helps to establish diagnosis and avoid lung biopsy in many patients.[102] On lung biopsy, finely vacuolated foamy macrophages are seen to fill the alveolar space along with the thickening of alveolar septa. Foamy macrophages also fill the lymphatic space around peripheral bronchioles, pulmonary artery branches and the interstitial tissues in subpleural area and interlobular septa. Pneumocytes and Clara cells remain unaffected.[102] Foamy changes have also been seen in ciliated epithelial cells. Inflammation and fibrosis are minimal and pulmonary architecture is usually preserved. In short, the histological picture can be described as diffuse endogenous lipoid pneumonia or alveolar proteinosis.[105]

Management

No specific therapy is available for ASM deficiency. Both ERT and gene therapy have shown promising results in the mouse model. Clinical trial of ERT in Niemann-Pick type disease is currently undergoing. Slow and inexorable progress is the natural history of respiratory disease. Treatment with whole lung lavage has been described with clinical improvement in isolated case reports.[105,108]

Hermansky-Pudlak Syndrome

Introduction

Hermansky-Pudlak Syndrome (HPS) is an autosomal recessive disorder characterized by the triad of oculocutaneous albinism, bleeding diathesis (secondary to defect in platelet function) and (in some cases) lysosomal accumulation of ceroid lipofuscin. Eight human subtypes have been described, each one resulting from mutation in one of eight different human genes. HPS has been described in many different ethnic groups; HPS1 is the most frequently described subtype; it is particularly common in individuals from North West Puerto Rico and accounts for approximately 50% of non-Puerto Rican cases. Mutations in both HPS1 and HPS4 genes have been described in Indian patients.[109,110]

Pathogenesis

The function of HPS genes is thought to involve intracellular vesicle formation and trafficking. The mutations of HPS genes cause defective formation, trafficking or function of intracellular lysosome-related organelles, e.g. melanosomes, platelet dense granules and lamellar bodies in alveolar type II pneumocytes.[111] A suggested mechanism for lung disease is that intracellular disruption of type II pneumocytes by ceroid deposition triggers a cascade of inflammation, cytokine production and fibroblast proliferation, leading to fibrosis. Interaction with external/environmental noxious stimuli has also been postulated to contribute to the development of fibrosis.

Pulmonary Manifestations

HPS causes interstitial lung disease. Pulmonary involvement has been described in HPS1 and HPS4.[109,112] Studies exploring pulmonary involvement in other subtypes of HPS are lacking. Lung fibrosis typically develops in the second or third decade of life in HPS1. In a series of 38 patients with HPS1, 61% had the onset of pulmonary symptoms at the mean age of 35 years.[113] However, a wide individual variability in clinical presentation and pulmonary function is known. Clinical presentation is akin to usual interstitial pneumonia: exertional dyspnea and dry cough are the usual presenting symptoms; physical examination is conspicuous for clubbing and velcro crepitations.[114]

Pulmonary function tests reveal restrictive physiology with reduced DL_{CO}. CXR shows bilateral reticulonodular opacities. HRCT scan shows septal thickening, ground glass pattern and mild reticulation in early cases; in the more advanced stages of disease, moderate to severe reticulation, traction bronchiectasis, subpleural cysts, and peribronchovascular thickening are seen. The changes have fairly even distribution within the lung zones with peripheral predominance.[115]

Diagnosis

This diagnosis can be suspected when a young patient presents with pulmonary fibrosis and shows typical ocular features, albinism and platelet dysfunction. Absence of platelet dense bodies on electron microscopy has been described as a rapid and reliable method of diagnosing HPS.[116] The diagnosis can also be established by the genotyping of DNA samples or the demonstration of ceroid accumulation in pathological specimens. Pathological examination of the lungs shows a picture of pulmonary fibrosis, architectural distortion and diffuse lymphocytic infiltration; in addition, a distinctive feature is the presence of large vacuolated histiocytes and pneumocytes containing periodic acid–Schiff (PAS) positive fine and coarse brown pigment within areas of interstitial fibrosis.[117] Numerous giant lamellar bodies can be seen in the macrophages and type II pneumocytes by ultrastructural examination. The fibrosis is also unevenly distributed without any subpleural or peribronchial predilection.

Management

Antifibrotic agent, pirfenidone has been tried in pulmonary fibrosis of HPS. Pirfenidone appears to slow progression of the disease when started at a stage when good residual function is still left.[118] As is true in many other chronic lung diseases, measures like the avoidance of smoking and environmental tobacco smoke, prompt treatment of respiratory infections, and administration of influenza and pneumococcal vaccines are recommended to preserve residual lung function.[113] In HPS patients with end-stage lung fibrosis, lung transplantation has been used successfully.[119]

Pulmonary fibrosis in HPS is usually fatal in fourth or fifth decade and accounts for death in ~50% of HPS patients.

Lipoid Pneumonia

Introduction

Lipoid pneumonia is a pattern of pathological involvement of lungs characterized by prominent deposition/filling of alveolar spaces with lipoid material. It can be called exogenous when the source of the aspirated lipoid material is from external sources and endogenous when the lipid deposition occurs without an exogenous source. Also called "cholesterol pneumonia," endogenous lipoid pneumonia typically occurs from accumulation of lipid-filled macrophages, surfactant and eosinophilic proteinaceous material derived from degenerating cells, in the alveoli distal to the bronchial obstruction. Diffuse intra-alveolar deposition of lipoprotein material, either as an idiopathic process or in the association of systemic diseases, e.g. chronic myeloid leukemia, is better termed pulmonary alveolar proteinosis (PAP). In this section, we will limit our discussion to exogenous lipoid pneumonia.

Pathogenesis

Exogenous lipoid pneumonia is an uncommon condition that occurs as a result of aspiration or inhalation of lipids: mineral oils (hydrocarbons obtained from petroleum), vegetable-based oils or animal fats. Mineral oils and vegetable-based oils cause milder inflammatory reactions with local encapsulation and fibrosis; animal fats, on the other hand, are hydrolyzed by lung lipases and the resultant free fatty acids trigger a severe inflammatory reaction, both in the alveolar space and the interlobular septa. Progression to fibrosis and end-stage lung disease may occur.

Risk Factors

Exogenous lipoid pneumonia has been reported in two settings: ingestion of paraffin for chronic constipation and the use of oily nasal preparations for rhinopharyngeal obstruction (often as a part of folk remedies).[120] In both scenarios, it involves aspiration of mineral oil that cannot be cleared by the lungs. Patients with the high risk of aspiration, due to anatomic or functional alterations of swallowing, such as patients with achalasia, gastro-esophageal reflux, scleroderma, Zenker diverticulum, and neurological and psychiatric disorders, etc. are at the increased risk of exogenous lipoid pneumonia. Accidental aspiration of isoparaffin and the development of exogenous lipoid pneumonia have also been reported as a peril of fire eating as a recreational activity.[121,122] Exogenous lipoid pneumonia, usually in the chronic form, has been described in a variety of industrial occupations involving the lubrication and cleaning of machinery and the spraying of pesticides or paints. It has also been reported as a result of embolization following rectal or subcutaneous administration of mineral oils. Rarely, it has been reported as a consequence of substance abuse, e.g. the inhalation of crack cocaine mixed with petroleum jelly or smoking of weed oil.[123,124]

Clinical Presentation

The clinical presentation depends on the volume and acuity of the aspiration episode(s). Acute exogenous lipoid pneumonia results as a consequence of aspiration of large amount of oil/hydrocarbons, e.g. accidental poisoning in children. Here the presentation is with acute respiratory symptoms: cough, respiratory distress and low-grade fever. Repeated aspirations of small amounts of lipids result in the chronic form of exogenous lipoid pneumonia. Here the onset of symptoms is insidious with chronic cough and/or dyspnea; fever, weight loss, chest-pain and hemoptysis are less common at presentation.[120,125] Often the presentation is that of nonresolving pneumonia. Sometimes, the patient may be present with chronic fibrosis. Auscultation of lungs may be normal or may reveal crepitations or wheezes. Lung function can be normal or may show a restrictive pattern, with reduced DL_{CO}.

Imaging Features

Different radiological patterns can be seen in the cases of lipoid pneumonia. In acute cases, radiological changes develop within the first few hours and usually within 24 hours. CXR and CT scan show: a. focal or multifocal consolidation with air bronchogram; b. areas of ground glass haziness; c. CT lesions typically with negative attenuation values (HU<0); d. pneumatoceles (as a late complication); e. pneumomediastinum, pneumothorax, and pleural effusions (rarely). The changes predominate in lower and middle lobes and are segmental or lobar in distribution. The radiologic manifestations of acute exogenous lipoid pneumonia improve or resolve over a variable period of time. Chronic lipoid pneumonia may show: a. multiple areas of low-attenuation consolidation (Figs 98.5A to D); b. areas of ground glass with septal thickening giving rise to a "crazy pavement" pattern; c. single or multiple nodules or masses resembling primary or metastatic lung cancer; d. predominant peribronchovascular and lower lobe distribution; e. architectural distribution and fibrosis in late cases.[126-130] False positive result with ^{18}F fluorodeoxy-D-glucose (FDG) positron emission tomography (PET) scan has been reported and may raise the suspicion of lung cancer.[128,131] The radiological manifestations of chronic lipoid pneumonia remain stable or slowly improve over time if exposure can be halted.

Diagnosis

Making a diagnosis of lipoid pneumonia requires a high degree of clinical suspicion and meticulous history taking. Diagnosis is difficult as the aspiration episodes are often unrecognized and clinical and radiological features mimic many other pulmonary diseases. On CT scan, the demonstration of fat-density areas within the lesions is considered diagnostic of lipoid pneumonia. Diagnosis can be confirmed by BAL. Fat globules are found in the bronchoalveolar fluid; cytological examination of the BAL fluid shows presence of lipid laden foamy macrophages.[132] Lung biopsy specimens show alveoli filled with macrophages containing lipid vacuoles (Fig. 98.6). Advanced lesions show larger lipid vacuoles surrounded by inflammatory infiltrates. Formation of giant cells and fibrosis are also seen.[133]

Management

Prompt identification and prevention of further aspiration prevent the progression of the disease, and in some cases allow resolution.[120,134] Anecdotal case reports of improvement with steroids are there; the beneficial effects in these cases may be attributed to the effect of steroids on the inflammatory process in lipoid pneumonia.[135-137] Similar results, however, have not been supported in data from large series.[120] Bronchoscopy with therapeutic BAL for the clearance of mineral oil from the lung parenchyma has been reported as the treatment for this condition. This strategy can lead to improvement in lung function, can prevent fibrosis and reduce the morbidity from lipoid pneumonia. Use of a fat emulsifier (sorbitan monooleate) during the lung lavage has also been reported.[138-140] BAL may not be effective in all cases, particularly in the chronic ones; each individual case should be carefully reviewed to decide whether therapeutic lavage will be effective.[120] The prognosis is generally good in most of the cases. However, complications like fibrosis, lung abscess formation, pleural effusion, bronchopulmonary fistula and bacterial/mycobacterial/fungal superinfection may occur. Infections with mycobacterial species like *M chelonae* and *M fortuitum* and fungal pathogens like *Aspergillus fumigates, Nocardia species,*[141,142] have been reported. These infections should be looked for when appropriate and treated.

Idiopathic Pulmonary Hemosiderosis

Introduction

Idiopathic pulmonary hemosiderosis (IPH) is an uncommon disease of unknown etiology characterized by the repetitive episodes of diffuse alveolar hemorrhage (DAH). The causes of DAH are diverse and other causes need to be excluded before a diagnosis of IPH can be reached.

Pathogenesis

The etiology of IPH remains unknown. Several theories have been proposed.[143] Familial clustering has been reported, which may suggest the inheritance of a rare genetic defect, predisposition and common exposure to environmental antigens. Suggestions of an autoimmune pathogenesis are based on indirect evidences like the presence of circulating immune complexes and the development of other autoimmune diseases in many patients of IPH who survive for more than a decade. An allergic theory has been proposed based on presence of antibodies against cow milk and coexistence with celiac disease.[144,145] Reports of the potential association of IPH and exposure to insecticides or fungal toxins have never been conclusively proven. A metabolic role of toxic oxidative radicals is likely to perpetuate lung

pathology in IPH. Alveolar macrophages have only a limited capacity for iron metabolism. After an episode of DAH, alveolar macrophage apparatus becomes exhausted and excess free iron can be present in the alveoli; within the alveoli, the free iron leads to the formation of highly reactive hydroxyl radicals, eventually leading to damage to alveolar structure and fibrosis.[146,147]

Clinical Presentation

About 80% of all cases of IPH occur in children, most of them being diagnosed in the first decade of life.[148] The rest of the cases are diagnosed in young adults, some of which may have remained undiagnosed till the adulthood.[143] Among adult patients, slight male preponderance is found. The clinical presentation widely varies. Some patients have a fulminant presentation with catastrophic DAH and respiratory failure. Some patients are present with the nonspecific symptoms of chronic cough and dyspnea. Recurrent hemoptysis is yet another presentation.[149] Patients may be present with symptomatic or asymptomatic anemia without any respiratory symptoms.[150] All adult patients report hemoptysis at some point of time. As the alveolar hemorrhage is intermittent, the waxing and waning of symptoms are usual in the clinical course. Exacerbations can occur during the tapering of steroids/immunosuppressive therapy. Other factors causing exacerbations are not clearly known. Fulminant DAH has been reported in the peripartum period.[151]

Pulmonary function tests reveal a pattern of restrictive ventilatory defect. Increased DL_{CO} is the hallmark abnormality in pulmonary function tests during an acute episode of DAH. When chronic changes of the disease, e.g. fibrosis sets in, DL_{CO} is low or normal.[152,153]

Laboratory and Radiological Features

Investigations often reveal hypochromic microcytic anemia, a reflection of repeated DAH, binding of iron with pulmonary hemosiderin (an unusable form) and iron loss in the sputum. Plasma ferritin level does not reflect the iron deficiency state, it is normal or elevated as a result of alveolar synthesis and subsequent release into the circulation of ferritin.[154] Bone marrow examination is consistent with an iron deficiency state. During or few days before an episode of bleeding, peripheral blood neutrophilia and eosinophilia may be seen.[155] During an acute phase of IPH, CXR reveals diffuse alveolar opacities and HRCT reveals bilateral ground glass opacities (Figs 98.7A and B). After multiple episodes of bleeding, chronic changes, evident as reticulonodular interstitial shadows, are seen on HRCT. Variable amount of fibrosis eventually develops.[156-158]

Diagnosis

Proof of intrapulmonary hemorrhage is an essential part of diagnosis of IPH. History of repeated episodes of cough, dyspnea and hemoptysis along with a consistent picture on CXR and HRCT, point towards the diagnosis. The demonstration of hemosiderin-laden macrophages in the sputum or in the BAL fluid confirms alveolar hemorrhage. Sometimes, the pulmonary hemorrhage is occult and the patient presents with iron deficiency anemia only; a comprehensive investigation of the cause is required before a diagnosis of IPH is suspected and established.[150,155] Serological studies for the markers of autoimmune diseases, e.g. antinuclear factor (ANF), antidouble-stranded DNA, antineutrophilic cytoplasmic antibody (ANCA, both perinuclear and cytoplasmic variants), antiglomerular basement membrane (GBM) antibody, antiphospholipid antibodies, IgG and IgE cow's milk antibodies and rheumatoid factor (RF) are negative.

A lung biopsy is required to rule out other causes of DAH. Transbronchial lung biopsy may be tried initially, if inadequate, video-assisted thoracoscopic biopsy or open lung biopsy can be obtained to get adequate tissue for study. Characteristic light microscopic features of IPH include: 1. the presence of intact or minimally fragmented erythrocytes in the distal airways and alveoli, an indication of recent alveolar hemorrhage; 2. hemosiderin-laden macrophages as an evidence of recurrent alveolar hemorrhage; 3. absence of vasculitis, granuloma, vascular malformation, neoplasm, infections, pulmonary infarct or evidence of any other lung disease. Thickening of the alveolar septae with the evidence of interstitial fibrosis is seen in the longstanding cases. Immunofluorescence and immunohistochemistry studies do not show any immunoglobulin or immune complex deposition, an important step to rule out autoimmune diseases causing

DAH.[159,160] Some authors suggest that celiac disease should be routinely looked for in patients with IPH.[144]

Management

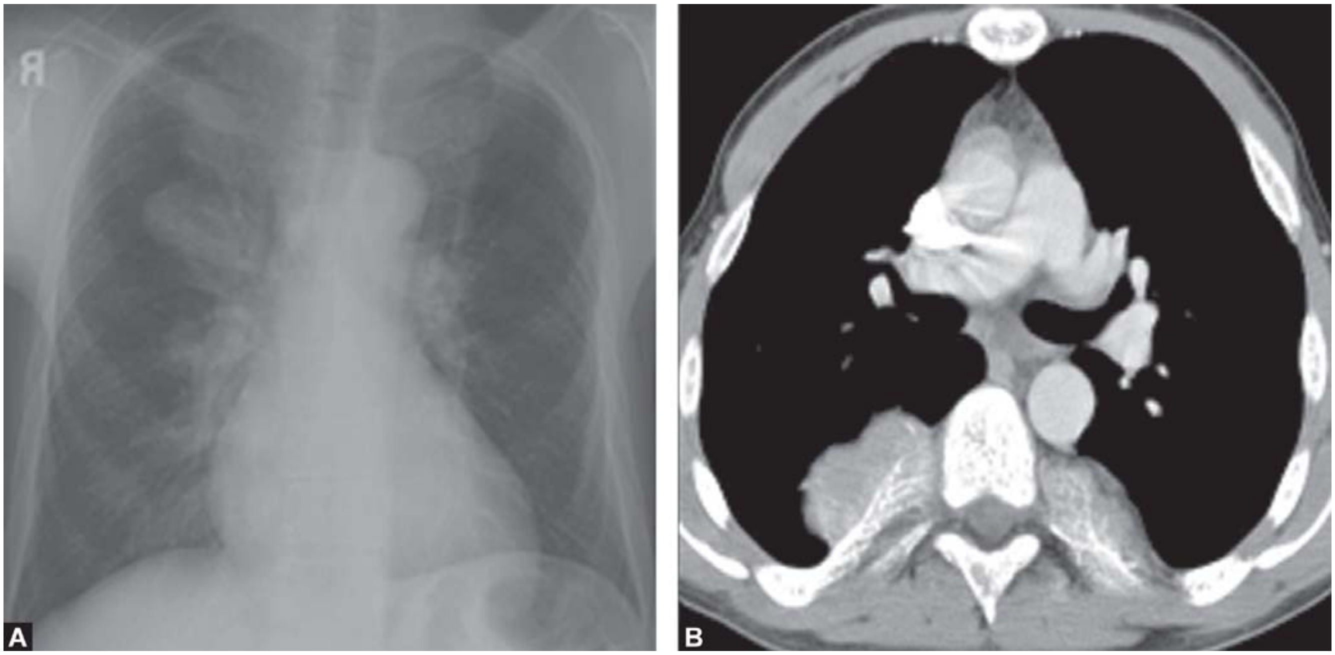
Systemic glucocorticoids remain the mainstay of treatment. Occasional reports of the successful use of inhaled corticosteroids are there, but the strength of evidence is not sufficient to support their use as a routine therapy.[143,161] Treatment, when started during an acute phase, helps to control symptoms and reduce mortality. Once started during the acute phase, steroids are continued till the new pulmonary infiltrates have resolved. A slow taper-off over a few months follows, if symptoms do not recur. Corticosteroids, when chronically administered, reduce the number of acute episodes and the occurrence of pulmonary fibrosis.[162,163] The indefinite administration of glucocorticoids, however, may lead to troublesome adverse effects; in some cases, symptoms may not be adequately controlled by corticosteroids. As maintenance therapy, various immunosuppressive agents, e.g. azathioprine, cyclophosphamide and chloroquine have been tried with or without corticosteroids, with variable success.[149,159,164-167] Cyclophosphamide infusion has been tried with success as a salvage therapy in IPH exacerbation with life-threatening DAH.[168] IPH patients, who had advanced chronic lung disease requiring lung transplantation, had recurrence of disease in the transplanted lung.[169]

Prognosis

IPH patients have substantial mortality from acute, severe DAH and significant morbidity from the recurrent episodes of bleeding and chronic lung disease. Prognosis and mortality vary in the reported literature.[163,170,171] In general, better outcome has been reported when prolonged immunosuppressive therapy has been used.[163] Prognosis is better in adult patients than in children and adolescents. No other clinical or biological parameter predicts prognosis in IPH.

Intrathoracic Extramedullary Hematopoiesis

In many hematological disorders, such as thalassemia, sickle-cell anemia, hereditary spherocytosis, polycythemia vera and myelofibrosis, intense compensatory hematopoiesis leads to the formation of foci of extramedullary hematopoiesis. Extramedullary hematopoiesis can be present within the thoracic cavity, described most frequently in patients with sickle-cell anemia and thalassemia.[172,173] Intrathoracic extramedullary hematopoiesis appears as paravertebral and/or paracostal masses. Formation of these masses occurs from the extrusion from the bone marrow through the cortex. A common site in the thorax is the costovertebral junction leading to a paraspinal mass. These masses have smooth, sharply defined margins, may be unilateral or bilateral in distribution (Figs 98.8A and B). No erosion of the adjacent



Figs 98.8A and B: Extramedullary intrathoracic hematopoiesis. CXR and CT scan showing bilateral multiple paraspinal soft tissue density opacities (*Courtesy:* Dr Rakesh Shah, Consultant radiologist, North Shore University Hospital, Manhasset, NY, US)

bone is seen. The masses may show initial rapid growth and subsequently remain stable in size. The patients usually do not have any symptoms attributable to the masses.[174]

Occasional cases with symptoms due to mass effect from the large foci of extramedullary hematopoiesis and other complications, e.g. exudative pleural effusion, hemothorax have been described.[172,175,176] In the case of presentation as intrathoracic masses, classic location and clinical setting make the diagnosis obvious; invasive diagnostic studies should be avoided. In symptomatic cases, a variety of treatment options may be tried. Blood transfusion (hypertransfusion) and hydroxyurea have been used with improvement in symptoms and should be the first line of treatment.[172,175] In cases where the lesions do not respond to the above, radiotherapy and surgical resection remain other treatment options. Pleural effusion and hemothorax are managed with pleural drainage and pleurodesis.[177]

Neurofibromatosis

Von Recklinghausen's disease or neurofibromatosis type 1 (NF) is an autosomal dominant disorder with characteristic neurocutaneous manifestations. Neurofibromatosis causes ILD. In an analysis of 64 cases of ILD in neurofibromatosis patients, the mean age of presentation of 50 years and a male preponderance was reported.[178] Most NF patients with lung involvement by ILD report dyspnea. Pulmonary function tests show an obstructive pattern with reduced DL_{CO}. CXR and HRCT show bilateral cystic lesions with upper lobe predominance.[179] Other radiological findings include ground-glass opacities, bibasilar subpleural reticular opacities and bullae. On pathological specimens, the involvement is patchy; areas of normal lung alternate with the areas of interstitial involvement. In the involved areas, the alveolar septae demonstrate lymphoplasmacytic inflammation and fibrosis consistent with nonspecific idiopathic pneumonia (NSIP) pattern. The etiological role of smoking in NF related ILD is debated, it has been suggested that smoking is the actual risk factor for the development and severity of ILD in NF patients.[180,181]

Outdoor Air Pollution and Respiratory Health

Sara Maio, Sandra Baldacci, Marzia Simoni, Fabio Cibella, Giovanni Viegi

INTRODUCTION

According to the Department of Chronic Diseases and Health Promotion of the World Health Organization (WHO), main chronic diseases include cardiovascular diseases (30% of projected total worldwide deaths in 2005), cancer (13%), chronic respiratory diseases (7%) and diabetes (2%). Chronic diseases are often defined as problems of ageing communities mainly caused by tobacco use, unhealthy diet and physical inactivity.[1] According to WHO, in Europe 86% of deaths are caused by chronic diseases.[2] However, chronic diseases are a large problem in low-income countries also (especially among those who do not have the resources to improve the quality of life). Recent evidence highlighted that deaths from cardiopulmonary diseases and lung cancer occur at earlier ages in low- and middle-income countries, where prevention is not a priority. It has been estimated that 35 million people died in 2005 due to stroke, cancer, and heart, respiratory and other chronic diseases. Only 20% of these deaths were in high-income countries, while 80% were in low- and middle-income countries.[3]

In an estimate of the proportions of total deaths and disability-adjusted life years (DALYs) lost in India, it was estimated that 53% of deaths were caused by chronic diseases, compared with 61% of deaths over the world, in 2005. Moreover, chronic diseases caused 44% of DALYs.[4] Compared to India, China showed higher estimates for chronic diseases mortality (80%) and DALYs (70%); there was the highest rate of death from chronic disease in middle-aged people.[5]

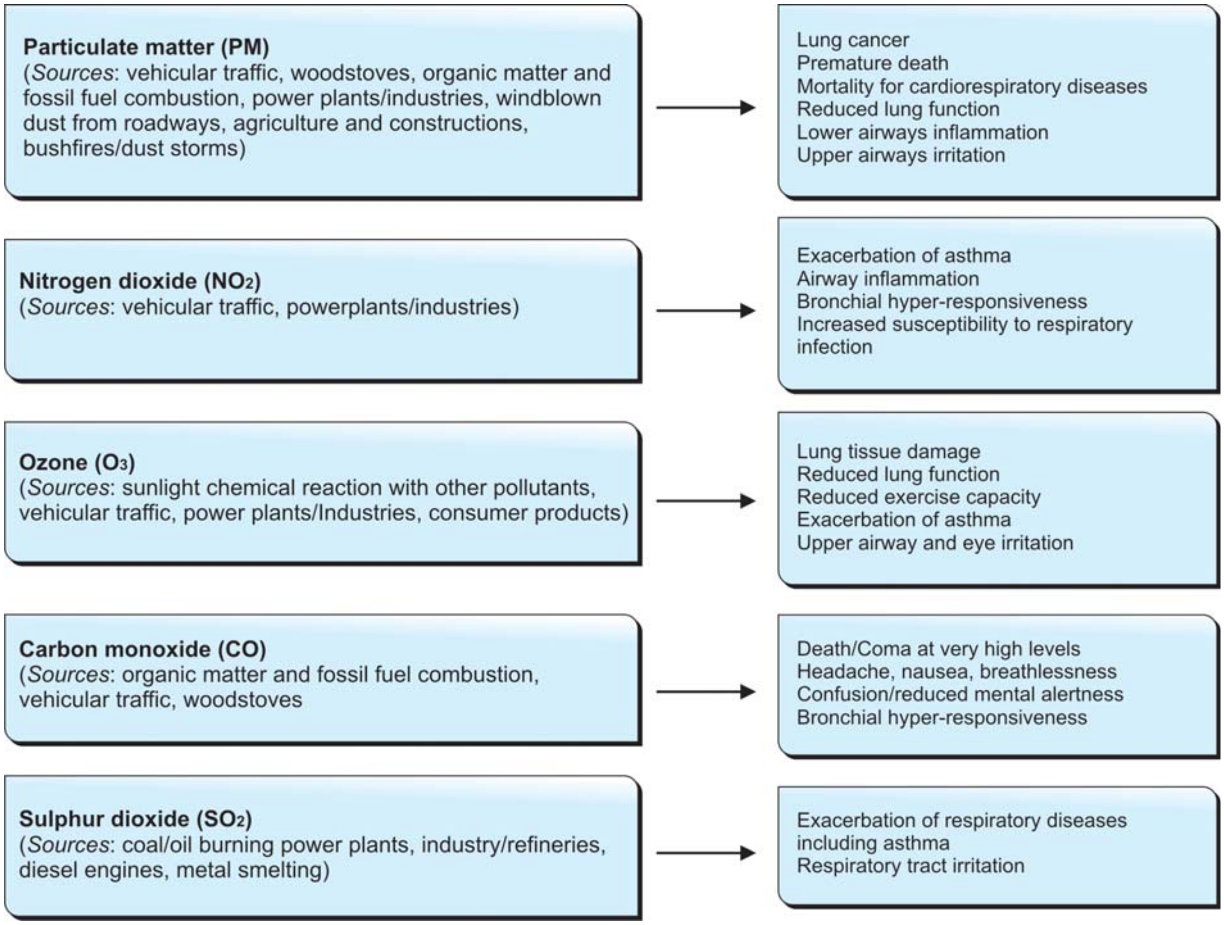
Using the WHO 2002 mortality estimates as a baseline, globally, about 58 million people died of chronic diseases in 2005.[3] This value is projected to rise to 64 million in 2015. The distribution of these deaths across three major cause groups showed a mortality of 30% for communicable, maternal, perinatal conditions, and nutritional deficiencies, of 61% for chronic and noncommunicable diseases and of 9% for injuries. In detail, respiratory diseases are the third leading single-cause of death worldwide (7%).[3]

OUTDOOR AIR POLLUTION EFFECTS

Air pollution represents an important risk factor for respiratory diseases. The statement of the American Thoracic Society published in the year 2000 was aimed at enlisting the respiratory health effects of air pollution, emphasizing the interpretation of the epidemiological evidence. The statement recognized the spectrum of responses to air pollution, which has been characterized as a pyramid, with the most common consequences of exposure (increased prevalence and incidence of respiratory symptoms/diseases, reduction of lung function, etc.) at the base and mortality, the least common and most severe consequence, at the tip.[6]

At the population level, respiratory diseases and related mortality have been increasingly associated with exposure to air pollutants. In the last years, the research about the effects of particulate matter (PM) with aerodynamic diameter <10 µm (PM_{10}) or <2.5 µm ($PM_{2.5}$) in relation to death for cardiopulmonary causes, originated much interest in the scientific community.

There is now firm evidence that PM, at low levels, has major effects on respiratory and on cardiovascular system, that traffic is a major source of harmful PM and



Particulate matter (PM)
(Sources: vehicular traffic, woodstoves, organic matter and fossil fuel combustion, power plants/industries, windblown dust from roadways, agriculture and constructions, bushfires/dust storms)
Lung cancer
Premature death
Mortality for cardiorespiratory diseases
Reduced lung function
Lower airways inflammation
Upper airways irritation
Nitrogen dioxide (NO2)
(Sources: vehicular traffic, powerplants/industries)
Exacerbation of asthma
Airway inflammation
Bronchial hyper-responsiveness
Increased susceptibility to respiratory infection
Ozone (O3)
(Sources: sunlight chemical reaction with other pollutants, vehicular traffic, power plants/Industries, consumer products)
Lung tissue damage
Reduced lung function
Reduced exercise capacity
Exacerbation of asthma
Upper airway and eye irritation
Carbon monoxide (CO)
(Sources: organic matter and fossil fuel combustion, vehicular traffic, woodstoves
Death/Coma at very high levels
Headache, nausea, breathlessness
Confusion/reduced mental alertness
Bronchial hyper-responsiveness
Sulphur dioxide (SO2)
(Sources: coal/oil burning power plants, industry/refineries, diesel engines, metal smelting)
Exacerbation of respiratory diseases including asthma
Respiratory tract irritation

Fig. 99.1: Main respiratory health effects by common outdoor pollutants

that public health improves in areas where PM pollution has been reduced (Fig. 99.1). Other important air pollutants are: "black smoke (particulates produced by fossil fuel) (BS)", carbon monoxide (CO), sulfur dioxide (SO_2), nitrogen oxides (NO_x) (products coming from vehicular-traffic and combustion processes), and ozone (O_3) (originated by photochemical reactions correlated to urban traffic) (Fig. 99.1).

Long-Term Effects

Many epidemiological surveys have shown that the long-term exposure to outdoor air pollutants is strongly associated with detrimental effects on respiratory health. In particular, a 16 year follow-up study carried out in US metropolitan areas on over half million people has evidenced that each 10 $\mu g/m^3$ elevation in fine particulate air pollution ($PM_{2.5}$) was associated with approximately a 6%, 9%, and 14%, increased risk of all-cause, cardiopulmonary and lung cancer mortality, respectively[7] (Table 99.1).

An European confirmation of the association between long-term air pollution exposure and cardiopulmonary mortality comes from a Dutch cohort (n=4492), where cardiopulmonary mortality was associated with living near a major road (relative risk 1.95, 95% CI 1.09–3.52) and, less consistently, with the estimated ambient background concentration (relative risk 1.34, 95% CI 0.68–2.64)[8] (Table 99.1).

The results of the investigation, the concentration-response relation of NO_2, PM_{10} and $PM_{2.5}$ with cause-specific mortality among all inhabitants of Oslo (Norway) suggest that the elderly and patients with chronic obstructive pulmonary disease (COPD) may have an increased risk of mortality at lower levels of pollutants with respect to general population.[9] Similarly, the results of study on the relation between long-term exposure to traffic air pollution and lung

TABLE 99.1: Long-term effects of outdoor air pollution (mortality and lung function)

Study	*Population sample investigated*	*Health outcome*	*Exposure*	*Measures (95% CI)*
Pope CA, 2002[7]	500.000 adults United States	Mortality: all-cause cardiopulmonary lung cancer	$PM_{2.5}$ (μg/m^3)	RR for an increase of 10 μg/m^3 of $PM_{2.5}$: 1.06 (1.02-1.11) 1.09 (1.03-1.16) 1.14 (1.04-1.23)
Hoek G, 2002[8]	4,492 subjects (55-69 years) Netherlands	Cardiopulmonary mortality	Living near major road	RR: 1.95 (1.09-3.52)
Gauderman WJ, 2004[12]	1,759 children (10-18 years) California	Clinical decrease of FEV_1	NO_2 (ppb) $PM_{2.5}$ (μg/m^3)	Correlation between average level, over eight-year period, of pollutants and low FEV_1
Shikowski T, 2005[10]	4,757 women (55 years) Germany	Pulmonary function and COPD	NO_2 (μg/m^3) PM_{10} (μg/m^3)	OR for an IQR range increase of pollutants (16 μg/m^3 NO_2; 7 μg/m^3 PM_{10}): 1.43 (1.23-1.66) 1.33 (1.03-1.72)
Gauderman W, 2007[11]	3,677 children California	Lung-function growth	Living near a freeway (500 m)	FEV_1: –81 mL, (–143 to –18) MMEF: –127 mL/s, (–243 to –11)
Rosenlund M, 2009[13]	1,195 children (9-14 years) Rome	Lung function	NO_2 (μg/m^3)	Changes for 10 μg/m^3 $NO_{2:}$ FEV_1/FVC: -0.62% (–1.05 to –0.19) FEF_{25-75}: -62 mL/s (–102 to –21) PEF: -85 mL/s (–135 to –35)

RR, relative risk; OR, odds ratio; PM_{10} and $PM_{2.5}$, particulate matter with aerodynamic diameter <10 μm and <2.5 μm respectively; NO_2, nitrogen dioxide; MMEF, maximum midexpiratory flow rate; FEF_{25-75}, forced expiratory flow between 25 and 75% of forced vital capacity; PEF, peak expiratory flow; FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity; IQR, interquartile; 95% CI, 95% confidence interval

function and exacerbations of COPD, showed that exacerbations of COPD were associated with a 7 μg/m^3 increase in five years mean of PM_{10} (interquartile range) [odds ratio (OR) 1.33, 95% CI 1.03–1.72] and with a 16 μg/m^3 increase in five years mean of NO_2 (interquartile range) (OR 1.43, 95% CI 1.23–1.66). Moreover, women living less than 100 meters from a busy road also had a significantly decreased lung function; among them, COPD was 1.79 times more likely (95% CI 1.06–3.02) than for those living farther away[10] (Table 99.1).

Analogous results were found in a sample of about 3,000 Californian children: those who lived within 500 m of a freeway had substantial deficits in 8-year growth of forced expiratory volume in one second (FEV_1) and maximum midexpiratory flow rate, compared with children who lived at least 1,500 m from a freeway[11] (Table 99.1).

The same research group following up children from the age of 10 to 18 years indicated that the current levels of air pollution have chronic adverse effects on lung development, leading to clinically significant deficits in maximal attained FEV_1 level as children reach adulthood, especially in boys. In particular there was a significant positive correlation between the deficit in the FEV_1 attained at the age of 18 years and the average level of exposure to NO_2 and $PM_{2.5}$[12] (Table 99.1).. In Italy, a strong association between estimated NO_2 exposure per 10 μg/m^3 increase and lung function decrease in children exposed to traffic-related air pollution was observed.[13] The exposure to air pollution is also associated with allergic respiratory symptoms/diseases. The detrimental effects of living near busy streets on respiratory health were confirmed by the results of the Swiss Cohort Study on Air Pollution and

Lung Diseases in Adults (SAPALDIA): living within 20 m of a main street increased the risks of regular phlegm by 15% (95% CI 1.00–1.31) and wheezing with breathing problems by 34% (95% CI 1.00–1.79) in never smokers[14] (Table 99.2).

More recently, associations between residential traffic and asthma and COPD in adults in southern Sweden were examined; the results showed that living within 100 m of a heavy road was associated with the prevalence of asthma diagnosis (OR 1.40, 95% CI 1.04–1.89), and

OR, odds ratio; $PM_{2.5}$, particulate matter with aerodynamic diameter <2.5 μm; NO_2, nitrogen dioxide; CO, carbon monoxide; SO_2, sulfur dioxide; NO_x, nitrogen oxide; COPD, chronic obstructive pulmonary disease; IQR, interquartile; 95% CI, 95% confidence interval

COPD diagnosis (OR 1.64, 95% CI 1.11–2.41)[15] (Table 99.2). A recent study assessed the association between exposure to air pollutants in a suburban area of India and the prevalence of asthma and respiratory disorders. Compared to subjects staying 5.0 km away from a main road, those subjects living within 0.5 km and 1.0 km showed an OR for doctor-diagnosed asthma of 3.57 (95% CI 3.00–3.95), and 3.00 (95% CI 2.85–3.50), respectively. The authors concluded highlighting the necessity to perform prospective studies considering the continuing rise in motorized vehicle use in India[16] (Table 99.2).

A study performed on two general population samples living in Northern Italy (rural area) and Central Italy (urban area) (areas with mean annual levels of total suspended particulate of 54 µg/m^3 and 94 µg/m^3, and values of sulfur dioxide of 8 µg/m^3 and 15 µg/m^3, respectively) pointed out that people living in urban area have an higher risk of having increased bronchial responsiveness (OR 1.41, CI 95% 1.13–1.76) with respect to people living in the rural area[17] (Table 99.2). A study in about 5,000 school children, living in six French cities, showed an important association between living in residential settings with $PM_{2.5}$ concentrations exceeding 10 µg/m^3 and asthma (OR 1.31, 95% CI 1.04–1.66) and atopic asthma (OR 1.58, 95% CI 1.17–2.14); this association was strengthened in long-term residents (current address for at least 8 years)[18] (Table 99.2).

Similar results were found in about 1,400 school children living in Shanghai for current asthma for 10 µg/m^3 increase in NO_2[19] and in 32,143 Taiwanese school children showing the prevalence of allergic rhinitis to be significantly associated with SO_2[20] (Table 99.2).

This results were confirmed in a Dutch birth cohort (n = 4000) that reported significant association between outdoor concentrations of traffic-related air pollutants ($PM_{2.5}$ and NO_2) and wheeze and asthma developed during the first four years of life[21] (Table 99.2). Recently, an Italian multicenter study (SIDRIA-2) showed independent association between car/truck traffic and current asthma symptoms and cough or phlegm; the stronger associations were found with truck traffic[22] (Table 99.2).

Short-Term Effects

Scientific evidence of the health effects of air pollution is not limited to studies of long-term exposure. In several cities throughout the world, consistent associations emerged between daily mortality, hospital admissions, emergency department (ED) visits and air pollutants concentration during the same or the previous few days. For the warm season, an increase in the 8-hour ozone concentration by 10 µg/m^3 was associated with a 0.31% (95% CI 0.17–0.52) increase in the total daily number of deaths, 0.46% (95% CI 0.22–0.73) in the number of cardiovascular deaths and 1.13% (95% CI 0.74–1.51) in the number of respiratory deaths[23] (Table 99.3).

In a study on the effect of $PM_{2.5}$ exposure on mortality in the nine cities of California, USA, for every increase of 15 µg/m^3 of $PM_{2.5}$, there was an increase of 0.61% (95% CI 0.18–1.04), 0.70% (95% CI 0.07–1.33) and 2.05% (95% CI 0.02–4.12) of total, cardiovascular and respiratory mortality, respectively[24] (Table 99.3). More recently, a time-series study of the acute effect of $PM_{2.5}$ and PM coarse on the increased risk of death for all causes, cardiovascular disease and respiratory diseases for the years 1999-2005 in 112 US cities showed a 0.98% increase (95% CI 0.751.22) in total mortality, a 0.85% increase (95% CI 0.461.24) in cardiovascular and a 1.68% increase (95% CI 1.04-2.33) in respiratory mortality for a 10-µg/m^3 increase in 2-day averaged $\mathbf{PM_{2.5}}$[25] (Table 99.3).

The association between daily air pollution levels ($PM_{10,}$ PNC–particle number concentration –CO, NO_2, O_3) and the occurrence of fatal, non-hospitalized coronary events was evaluated (referred the association); the association was statistically significant for PNC, PM_{10} and CO. The effect was stronger among people over 65 years of age, but was not limited to a group with specific comorbidity, even if there was a major risk in subjects with COPD[26] (Table 99.3).

The MISA study (the Italian Meta-analysis of Short-term effect of Air pollution) dealt with the effect of the exposure to air pollution in 15 Italian cities, summing up to 9.1 million inhabitants at the 2001 census. The results showed an increase of mortality for all natural causes associated to the increase of air pollutants concentration. Similar findings were found for cardiorespiratory mortality and hospital admissions for respiratory and cardiac diseases[27] (Table 99.3).

In Shanghai, China, a time-series analysis to assess the effects of major air pollutants and daily mortality, was also conducted. In the single-pollutant models, an increase of 10 µg/m^3 of PM_{10}, SO_2, NO_2 was associated with mortality from all causes and from cardiopulmonary diseases; a significant effect was found on daily mortality for NO_2 and SO_2 after adjusting for PM_{10}, in the multipollutants model[28] (Table 99.3). Another study performed in Shanghai assessed the association between outdoor air pollutants (PM_{10}, SO_2, and NO_2) and total hospital outpatient visits. In particular, for lag 3 (pollutant concentration level three days before

TABLE 99.3: Short-term effects of outdoor air pollution (mortality)

PM_{10} and $PM_{2.5}$, particulate matter with aerodynamic diameter <10 μm and <2.5 μm respectively; PNC, particle number concentration; NO_2, nitrogen dioxide; O_3, ozone; CO, carbon monoxide; IQR, interquartile; 95% CI, 95% confidence interval

the events), a 10 μg/m^3 increase in concentration of PM_{10}, SO_2 and NO_2 corresponded to 0.11% (95% CI – 0.03-0.26%), 0.34% (95% CI 0.06-0.61%) and 0.55% (95% CI 0.14-0.97%) increase of outpatient visits[29] (Table 99.4). Data of daily emergency hospital admissions was assessed for COPD in 15 major hospitals in Hong Kong and indices of air pollutants like SO_2, NO_2, O_3, PM_{10} and $PM_{2.5}$: relative risks for admission for every 10 μg/m^3 increase were 1.007, 1.026, 1.034, 1.024 and 1.031, respectively[30] (Table 99.4).

For estimating risks of cardiovascular and respiratory hospital admissions associated with short-term exposure to $PM_{2.5}$, a national database comprising daily time-series data on hospital admission rates for 204 US urban counties (population >200,000) was analyzed for the years 1999–2002. There was a significant increase in the hospitalization rate for COPD and respiratory tract infections per each 10 µg/m^3 increase of $PM_{2.5}$ in the elderly[31] (Table 99.4). The association between gaseous pollution and hospitalization for COPD among elderly people living in Vancouver, British Columbia, Canada (1994–1998) was examined. The combined relative risk for an increase of interquartile range of 7-days, average level of NO_2, CO, O_3 and SO_2, on COPD hospitalization was 1.21[32] (Table 99.4).

A recent study performed in Canada showed an association between outdoor air pollution levels and ED visits for asthma. In particular, an increase in the interquartile range of the 5-day average for NO_2 levels was associated with a 20% increase in the number of ED visits, whilst an increase in the interquartile range of the same day average for $PM_{2.5}$ levels was associated with a 12% increase in the number of ED visits, among subjects over 75 years[33] (Table 99.4). A similar study was conducted in 15 major hospitals of Hong Kong, finding a relative risk for asthma hospitalization of about 1.02 for every 10 µg/m^3 increase in NO_2, O_3 and $PM_{2.5}$, in subjects of age 15–65 years; the younger age group (0–14 years) tended to have a higher RR for each 10 µg/m^3 increase in pollutants than, those aged 15–65 years[34] (Table 99.4).

Another important time-series analysis was conducted on about 400,000 ED visits to 14 hospitals in seven Canadian cities. Associations were examined between CO, NO_2, O_3, SO_2, PM_{10} and $PM_{2.5}$, and visits for cardiovascular and respiratory diseases. 24-hour average concentrations of CO and NO_2 (lag 0 days) showed associations with increase in visits for myocardial infarction/angina (2.1%, 95% CI 0.0–4.2% and 2.6%, 95% CI 0.2–5.0%, respectively); O_3 (lag 2 days) was most consistently associated with increases in asthma visits (3.2%, 95% CI 0.3–6.2%)[35] (Table 99.4).

The association between hospital admission for cardiovascular and respiratory diseases and daily levels of $PM_{2.5}$ chemical components in 119 US urban communities for 12 million Medicare enrollees ($\geq$ 65 years of age) was investigated. In multiple-pollutant models, an interquartile range (IQR) increase, in elemental carbon was associated with a 0.80% increase in the risk of same-day cardiovascular admissions, and an IQR increase in organic carbon matter was associated with a 1.01% increase in the risk of respiratory admissions on the same day[36] (Table 99.4). A similar relationship was found for pneumonia; a significantly elevated rate of pneumonia hospitalizations was seen in subjects over 65 years, associated with BS, $PM_{2.5}$ and CO.[37] Another study, conducted in 36 US cities on respiratory hospital admissions in the elderly in the period 1986–1999, assessed that, during the warm season, a 5-ppb increase in O_3 was associated with a 0.42% increase in pneumonia admissions. Also, a 10 µg/m^3 increase in PM_{10} during the warm season resulted in a 0.79% increase in pneumonia admissions[38] (Table 99.4).

With regard to the association between outdoor air pollution and tuberculosis (TB), the exposure to PM-associated transition metals, e.g. iron, producing oxidative stress in the lung, could adversely affect the progression of TB. Only few studies of outdoor air pollution and TB have been reported, indicating that outdoor air pollution might have a negative impact on TB infection and/or progression of disease.[39]

Prevention

There are clear evidences on the benefits of exposure reductions. More than 70% of chronic bronchitis cases could be prevented, if the prevalence rates of active smoking, environmental tobacco smoke and PM_{10} annual mean were reduced to 5%, 2.5%, and 5 µg/m^3, respectively.[40] Moreover, a Swiss recent study showed that a decline of 10 µg/m^3 of PM_{10}, over an 11-year period, reduced the annual rate of decline in FEV_1 by 9% and of the FEF_{25-75} by 16%.[41]

Previously, an association of the prolonged reduction in ozone, due to the traffic changes in Atlanta, Georgia, USA, during the 1996 Summer Olympic Games, was shown with significantly lower rates of childhood asthma events. These data provide support for efforts to reduce air pollution and improve health via reductions in motor vehicle traffic.[42] A rather moderate decline of air pollution levels in the 1990s in Switzerland was associated with a reduction in respiratory symptoms and diseases in school children. The results showed a decline of the prevalence of chronic cough, bronchitis, common cold, nocturnal dry cough and conjunctivitis symptoms.[43] A more recent study assessed whether, a ban on diesel-powered motor vehicles in Lebanon reduced emergency respiratory admissions for children (< 17 years of age) in Beirut. A significant reduction in admissions for asthma and upper respiratory tract infection from one year, pre-ban to one year, post-ban has been recorded.

TABLE 99.4: Short-term effects of outdoor air pollution (hospital admissions and emergency department visits)

Study	*Population sample investigated*	*Health outcome*	*Exposure*	*Measures (95% CI)*
Peng RD, 2009[36]	12 million subjects ($\geq$65 year) 119 US urban communities	Hospital admission: respiratory cardiovascular	EOC of $PM_{2.5}$ EC of $PM_{2.5}$	Increase % in risk for an increase of the IQR range of air pollutant (3.18 μg/m^3 EOC; 0.40 μg/m^3 EC): 1.01 (0.04-1.98) 0.8 (0.34-1.27)
Stieb DM, 2009[35]	ED visits in 14 hospitals of seven Canadian cities	ED visits for asthma	O_3	Increase % in risk for daily average air pollution: 3.2 (0.3-6.2)

*PM_{10} and $PM_{2.5}$, particulate matter with aerodynamic diameter <10 μm and <2.5 μm respectively; BS, black smoke; CO, carbon monoxide; O_3, ozone; NO_2, nitrogen dioxide; 95% CI 95%, confidence interval; OR, odds ratio; RR, relative risk; EOC, elemental organic carbon; EC, elemental carbon; ED, emergency department visits; IQR, interquartile; 95% CI, 95% confidence interval

Unfortunately, this finding is weakened by the absence of evidence from air quality monitoring and speciation of particulate matter, which are lacking in most developing countries.[44]

There is little direct evidence that diminished particulate air pollution concentrations would lead to reductions in death rates. A study reported the effect of air pollution controls (i.e. the ban on coal sales) on particulate air pollution and death rates in Dublin: in connection with a decline in average BS concentrations of 35.6 μg/m^3 (70%), decreases of adjusted non-trauma death rates (5.7%), respiratory deaths (15.5%), and cardiovascular deaths (10.3%) were shown.[45] A recent confirmation comes from the Harvard Six Cities adult cohort study that showed an association between reduced $PM_{2.5}$ concentrations and reduced mortality risk: RR 0.73 (95% CI 0.57–0.95) for total mortality, RR 0.69 (95% CI 0.46–1.01) for cardiovascular mortality and RR 0.43 (95% CI 0.16–1.13) for respiratory mortality.[46]

Conclusion

Although outdoor air pollution levels are highest in the cities of developing countries, few studies took into account the association between air pollutants exposure and respiratory health in these realities; indeed, studies performed in other countries indicate the detrimental effects of air pollution on respiratory health also below the reference values of air quality, especially in susceptible population like, children and elderly. For this reason, national and international respiratory societies, respiratory physicians, as well as public health professionals, should advocace for a cleaner environment.

According to the 2007 ERS position paper about particulate matter, science and European Union (EU) policy,[47] neither the $PM_{2.5}$ annual average of 25 μg/m^3 nor the target value proposed by EU Parliament on September 26, 2006 (20 μg/m^3) are sufficient to adequately protect public health. Indeed, there is sufficient epidemiological evidence pointing to the necessity of promulgating air pollution standards in both developed and underdeveloped countries, which set the long-term air quality guideline for $PM_{2.5}$ to 10 μg/m^3.[48] Implementation of strategies, which allow to respect stringent air pollution standards require more resources, but the health benefits gained from the reduction of air pollution clearly outweigh these costs.

Indoor Air Pollution and Respiratory Health

Marzia Simoni, Sara Maio, Sandra Baldacci, Fabio Cibella, Giovanni Viegi

INTRODUCTION

Indoor environments contribute significantly to total human exposure to air pollutants. Exposures occur in places where people spend time and globally, people spend the majority of their time indoors. The same quantity of a pollutant causes more exposure when, released indoors than outdoors. For some pollutants, indoor exposure probably dominates the global human exposure. Approximate estimates indicate that about 85% of all global Particulate Matter (PM) pollution occurs indoors.[1] Some pollutants may be 2–5 fold more concentrated inside, than outside the buildings; furthermore, indoor pollutants may have an important biological impact even at low concentrations over long exposure periods.

Indoor Air Pollution (IAP) represents a substantial risk for human health, particularly for children (their defense mechanisms are still evolving, and they inhale a higher volume of air per body weight than adults), elderly people, subjects with cardiorespiratory diseases, subjects at higher risk for specific exposures, or for the socioeconomically deprived.[2] The largest health impacts occur among the poorest and the most vulnerable populations, such as those living in Low-Middle-Income Countries (LMIC), especially in Least-Developed Countries (LDC), where people suffer from the conditions of extreme poverty; conflicts and wars; lack of political and social stability; and often the authoritarian form of government.[3]

Indoor exposure mainly occurs at home and in workplaces/schools, but also in day care centers, social recreation settings, or microenvironments, such as cars, buses, trains, subways and airplanes.

Indoor Pollutants and Related Sources

Anthropogenic agents and allergens are two common groups of indoor pollutants (Fig. 100.1). Most indoor pollutants derive from anthropogenic activity (combustion processes, redecorating/remodeling/repair or cleaning activity). The main sources are two: Combustion of solid fuels for cooking/heating, and Environmental Tobacco Smoke (ETS).[3]

Biomass fuel is the primary source of domestic fuel in developing nations, frequently burnt in the households in open fire or inefficient stoves. The consequence is a large production of smoke, containing many substances harmful for health (PM, carbon monoxide, nitrogen oxides, polycyclic organic hydrocarbons, etc.), derived from incomplete combustion. In houses where biomass fuels and coal are used, PM levels may be 10–50 times higher than the guideline values for good Indoor Air Quality (IAQ). About 3 billion people (almost half of the humanity) rely on solid fuels for cooking/heating, with little or no access to the modern forms of energy. The World Health Organization (WHO) reports that, globally, about 1.5 billion people have no access to electricity, and more than 80% of them live in sub-Saharan Africa and South Asia. In Chad, Liberia, and Burundi, 95% of people lack electricity access, as well as 62% in Haiti, and 25% in South Africa (but only 2% in Brazil and less than 1% in Mauritius). Only 27% of people relying on solid fuels use improved cooking stoves (6% in LDC and sub-Saharan Africa). Traditional biomass, such as wood, charcoal and dung is much more commonly used in rural than in urban areas.[3]

Environmental tobacco smoke (ETS) is the largest contributor to indoor PM in buildings where, people

smoke, accounting for up to 50-90% of the total PM concentration. WHO estimates around 1.3 billion smokers in the world (84% in developing countries).[4] About 40% of smokers in the world live in China and India. In the developed countries, people are stopping smoking, while in the developing countries, tobacco sales are on the rise. More than 20% of low-income countries have no (or no recent/no representative) national smoking prevalence data for adults or youth. Globally, about one third of adults are regularly exposed to ETS.[5] The global prevalence of ETS exposure among young people is still high. In 2008, 43% of adolescents were living in homes where, other people smoke[5] (Fig. 100.2).

Indoor Pollutants and Health Effects

The scientific interest for IAP and possible effect on human health began in early 80s and keeps increasing. Poor IAQ poses a risk to the health of over half of the world's population, especially affecting the poor people. IAP results as the eighth most important risk factor, being responsible for 2.7% of the global burden of disease (between 1.5 and 2 million deaths yearly).[6] There is consistent evidence that the exposure to IAP increases the risk for several respiratory/allergic symptoms/diseases[6,7] (Fig. 100.3).

Health Effects From Biomass Exposure

From a global point of view, the health consequences of IAP from biomass fuels are comparable to those of tobacco use.[8] Never smoker Mexican women exposed to wood smoke have a five-fold risk for chronic bronchitis and chronic airflow obstruction as compared to the unexposed.[9] Never smoker women exposed domestically to biomass develop Chronic Obstructive Pulmonary Disease (COPD) with clinical characteristics, quality of life, and increased mortality similar in degree to that of tobacco smokers.[10]

The exposure to biomass fuels is strongly poverty-related, consequently is a major health concern in the

developing world, especially for children and women, who generally spend much time in the kitchen for cooking.

The strongest evidence of biomass burning effect, concerns acute lower respiratory infections (ALRI, i.e. pneumonia), in children, and COPD and lung cancer in adults. WHO[3] estimates the use of solid fuel to be responsible for about 2 million deaths per year from these diseases (3.3% of all deaths, globally). More than 99% of these deaths occur in developing countries (Fig. 100.4). The fraction of deaths from these three diseases, which can be attributed to solid fuel, is 38% in all developing countries. More than 50% of deaths occur in LDC and sub-Saharan Africa (Fig. 100.5). About 60% of deaths from COPD and lung cancers, attributable to solid fuels, occur in women (Fig. 100.6). A recent Chinese study suggests, for the first time that indoor air pollution from unvented coal burning is an important risk factor for pneumonia death, also in adults.[11]

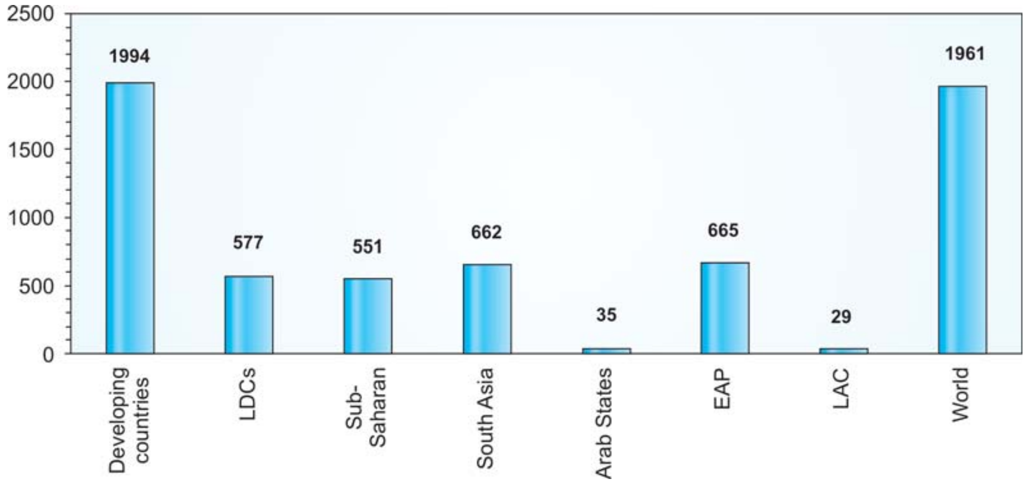

Fig. 100.4: Number ('000) of deaths from pneumonia, COPD, and lung cancer. LDCs, Least Developed Countries; EAP, East Asia and the Pacific; LAC, Latin America and the Caribbean. Original data are from World Health Organization[3]

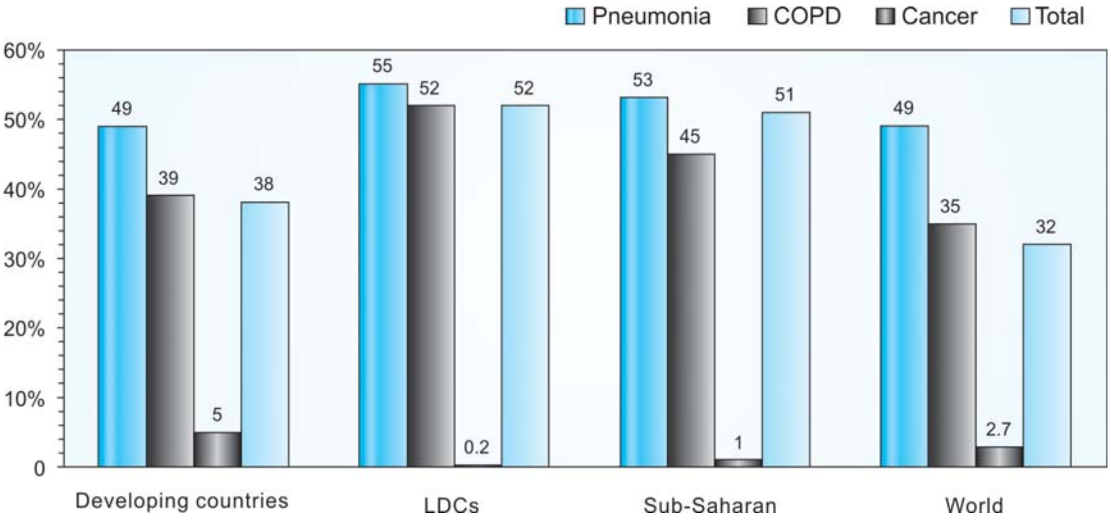

Fig. 100.5: Percent of deaths attributable to solid fuel, by disease. LDCs, Least Developed Countries. Original data are from World Health Organization[3]

The association of biomass burning with ALRI, in children of less than 5 years yields a Relative Risk (RR) of 2.3 (95% Confidence Interval, CI, 1.9–2.7), while RRs for COPD from biomass exposure and lung cancer from coal smoke exposure, in women, are 3.2 (2.3–4.8), and 1.9 (1.1–3.5), respectively.[12] In South Africa, Zimbabwe, Nigeria, Tanzania, Gambia, Brazil, India, Argentina, Nepal and Kenya, children exposed to biomass fuel have a risk for ALRI two to three times higher than unexposed or less exposed (ORs range from 2.2 to even 9.9).[13] Ezzati and Kammen, in 2001, evaluated for the first time, data on exposure-response relationships between PM and incidence of ALRI, in children and adults living in rural Kenya: the trend of increasing risk with higher levels of exposure was highly significant.[14]

Moderate evidence has been found for the associations of biomass exposure with COPD in men (RR 1.8, 1.0–3.2), asthma in children (RR 1.6, 1.0–2.5), asthma and tuberculosis in all (RR 1.2, 1.0–1.5, and RR 1.5, 1.0–1.4, respectively), and lung cancer in women (RR 1.5, 1.0–2.1). Coal exposure is also moderately related to lung cancer in men (RR 1.5, 1.0–2.5).[12] A meta-analysis on data from Africa, Latin America and China,[15] as well as epidemiological studies performed in India,[16-18] Tanzania,[19] China,[20,21] Ecuador,[22] Zimbabwe,[23,24] Iran,[25] and Bangladesh,[26] show

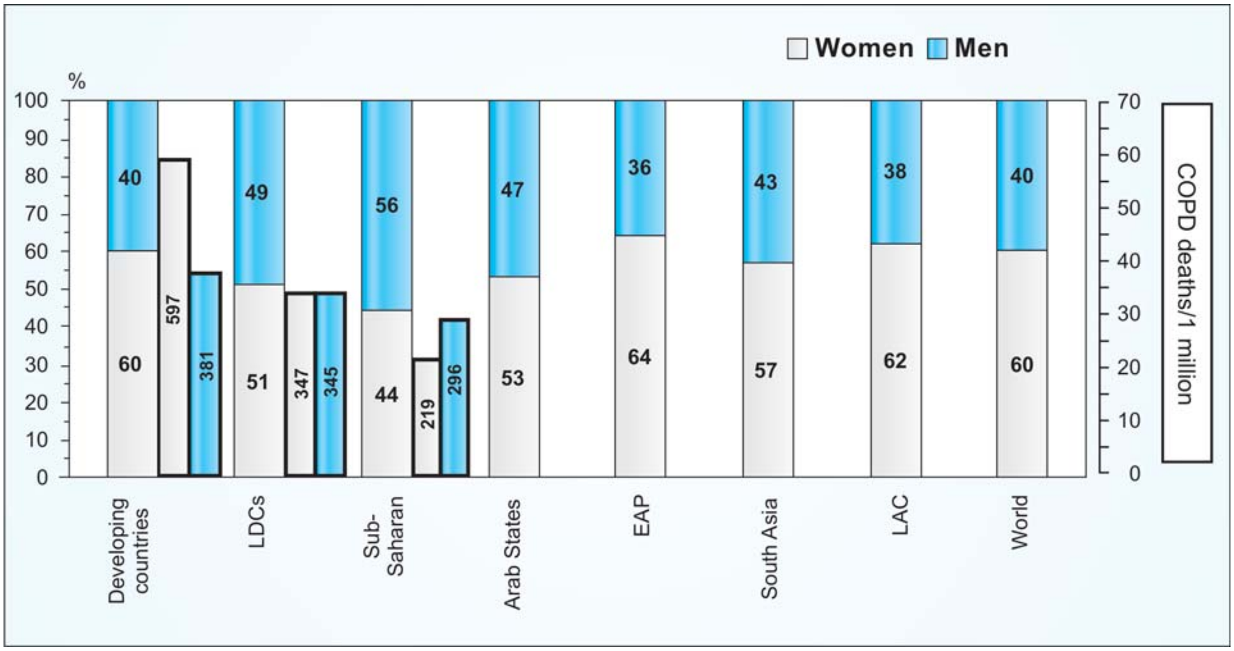

Fig. 100.6: Distribution (%) of deaths for COPD and cancer attributable to solid fuel in women and men, and rate per 1 million people of COPD deaths attributable to solid fuel, by gender. associations between biomass fuel use and acute respiratory illnesses, respiratory symptoms (including persistent cough/phlegm, shortness of breath, chest tightness, wheezing or whistling chest), or impaired lung function (Table 100.1).

In 2006, the Working Group (WG) of the International Agency for Research on Cancer (IARC) concluded that indoor emissions from household combustion of coal are "carcinogenic to humans (Group 1)," and those from household combustion of biomass fuel (mainly wood) are "probably carcinogenic to humans (Group 2A)."[27]

Health Effects of ETS

Environmental tobacco smoke kills 600,000 people each year,[5] and is linked to several acute and long-term adverse respiratory effects, including lung cancer and tuberculosis. There exists a pooled risk for chronic cough in men (OR 1.60, 95% CI 1.22–2.10) and women (1.68, 1.17–2.34) exposed to ETS.[28] Women have higher risk for ETS exposure than men, and many respiratory symptoms/diseases have been related to smoke exposure from husbands.[29]

There is also strong evidence that ETS exposure, in adults, is related to new-onset asthma,[30] and that exacerbates preexisting COPD and asthma, as also confirmed by an Indian study, where adults exposed to ETS showed higher prevalence of asthma and asthma exacerbation than unexposed ones.[31]

In children, there is a consistent evidence of adverse effects from parental smoking for wheezing [ORs ranging from 1.17, 95% CI 1.02–1.33 (early exposure) to 1.25, 1.14–1.37 (fetal exposure)], asthma (mean OR 1.18, 1.08–1.28, for mother's smoking during pregnancy), and bronchitis (mean OR 1.10, for early or current passive smoking).[32] Through a meta-analysis, which also included African countries, the pooled OR for asthma in children was reported as 1.37 (1.15–1.64).[33] Another meta-analysis on the relationship between parental smoking and ALRI in children (38 studies from 14 European and non-European countries) estimated a pooled OR of 1.57 (1.42–1.74) for children with both parents smoking, 1.72 (1.55–1.91), and 1.29 (1.16–1.44), for children with either the mother or the father smoking, respectively.[34]

There are very few reports on the health effects from ETS exposure in the LMIC. Most studies concern Indian samples (Table 100.2). Most studies concern Indian samples. In Indian adolescents, passive smoking was associated with an increased risk of asthma, and with a variety of respiratory symptoms, with ORs ranging

from 1.60 to 2.25.[31] Yet, in India ETS exposure increased approximately three-fold the risk for asthma in schoolchildren,[35] and affected pulmonary function, even if only in children exposed also to biomass fuels.[36] A significant inverse association of ETS exposure with pulmonary function was found among children living in Ecuador.[22] Recently, ETS exposure was a significant risk factor for acute respiratory illnesses in Indian infants.[16] Dose-response effects have been found for bronchitis and pneumonia in Chinese infants, as well.[37]

The causal role of ETS exposure in lung cancer development is well-established. ETS is classified as a class A carcinogen, responsible for about 20% of lung cancers in nonsmokers. The pooled risk from spousal smoking for lung cancer in never smokers is OR 1.18 (1.01–1.37) [for ever exposure] and 1.23 (1.01–1.51) [for long-term exposure]. Similar ORs are seen for ETS exposure in the workplace and in social settings [1.16, 0.99–1.36 (for ever exposure) and 1.27, 1.03–1.57 (for long-term exposure)].[38] Through a meta-analysis that also includes data of China, Japan and Taiwan, RRs for lung cancer are 1.20 (1.13–1.92) in nonsmoker women ever exposed to husband's ETS, and 1.16 (1.05–1.28) in those ever exposed to ETS at work.[39] RRs for lung cancer in never-smoking women exposed to husband's smoking were evaluated: 1.15 (1.03–1.28) in North America, 1.31 (1.16–1.48) in Asia, and 1.31 (1.24–1.52) in Europe.[40] In India, the risk for lung cancer was found to be about four-fold higher in those exposed to ETS during childhood (the highest risk was found for women), and increased with increasing number of smokers and duration of exposure (Table 100.2). In this study, lung cancer was weakly related to ETS exposure at the workplace, with a dose-response effect by the number of years of exposure; interestingly, a positive association between ETS exposure in vehicles and lung cancer in nonsmokers was also found.[41] In Morocco, passive smoking increased the risk of lung cancer, but not significantly (OR 1.36, 0.71–2.62).[42]

Less known is the link between ETS and tuberculosis. A recent cohort study on 15,486 never-smoking married women (age 65 to 74 years), performed in China (where the prevalence of current smokers is 60% in men and only 4% in women), shows that women exposed to ETS at home have higher risk for COPD (Table 100.2), and more likely develop tuberculosis (hazard ratio 1.49, 95% CI 1.01–2.19).[43]

Other Indoor Exposures

Dampness/moulds are present in 10 to 50% of houses in affluent countries. Although few data are available, the magnitude of the problem appears similar in LMIC. The exposures to building dampness and moulds are associated with approximately 30 to 50% increase in a variety of respiratory and asthma-related health outcomes (asthma diagnosis/development, upper respiratory tract symptoms, cough, wheeze, dyspnea, bronchitis, allergic rhinitis and respiratory infections).[44] In a Chinese subtropical area, dampness at home was very common and was a strong predictor of respiratory symptoms, in children: the risk by dampness/moulds exposure was OR 1.37 (1.03–1.83) [for allergic rhinitis] and 5.74 (2.20–14.95) for cough].[45]

The exposure to Volatile Organic Compound (VOCs) in developing countries is likely related to the wood smoke from cooking/heating that, contains also VOCs, such as, aldehydes (e.g. formaldehyde). Many studies indicate health effects from very low levels of VOCs exposure, commonly found at the population level. The exposure to VOCs may result in, effects ranging from irritation to cancer.

In children, ORs for asthma diagnosis range from 1.2 to 2.9.[46] Many of the effects reported in children are also seen in adults. An increasing concern is addressed to exposure to VOCs from cleaning activity, which involves both the general population and a large fraction of workers, and constitutes a risk factor for asthma.

Occupational Exposure

Occupational exposure, which will be treated extensively in other parts of this book, deserves a brief comment herein. It does not involve the general population, but it is important for specific groups of workers, that can be exposed indoors to inorganic dust, wood dust, fumes, gases and cleaning agents.

Occupational exposure is an important risk factor for respiratory health independently of tobacco smoke. The population attributable risk for occupational asthma is quite similar in the developed and the developing countries with rapid industrialization (13% to 15%), and lower in other developing countries (6%).[47] However, occupational asthma remains under-recognized, especially in LMIC.

The median population attributable risk for either chronic bronchitis or airflow obstruction in different countries, including China, ranges from 15% to 19%.[48] In Iran, among the employees of cement and ceramic industries, exposed workers to raw materials showed significantly higher prevalence of cough, phlegm, dyspnea and wheezing; in the cement industry, only exposed workers showed abnormal findings at chest X-ray.[49,50]

The highest risk in developing countries seems to be related to cleaning agents and pesticide exposure.[47] In Saudi Arabia, in chemical fertilizer producing factories, the workers exposed to the high levels of ammonia had a significantly higher relative risk for cough (3.48, 1.84–6.57), wheezing (5.01, 2.38–10.57), phlegm (3.75, 1.97–7.11), dyspnea (4.57, 2.37–8.81), and bronchial asthma (4.32, 2.08–8.98).[51] In Pakistani wood industries, the increased duration of wood dust exposure resulted significantly and inversely related to peak expiratory flow.[52]

Among cancers linked to occupational exposures, lung cancer is the most common. Recent extrapolation from cohort studies on miners, suggests radon as the second leading cause of lung cancer death after tobacco smoke.[53] In India, the lifetime risk of lung cancer due to indoor radon exposure, for the total population, of three studied areas, was 0.67%.[54]

PREVENTION AND CONCLUSIONS

Programs and public health initiatives to reduce exposures to indoor air pollution need to be adopted in LMIC. Among Chinese coal users, a stove improvement (higher ventilation by installing a chimney) was associated with a 50% reduction in pneumonia deaths.[11] In Guatemala, among Mayan women, all using traditional indoor open fires, the use of a chimney woodstove (plancha) significantly reduced carbon monoxide exposure by 61.6%, and the risk for all respiratory symptoms: the reduction was statistically significant for wheeze (RR 0.42, 95% CI 0.25-0.70). The number of respiratory symptoms reported by the women at each follow-up point was also significantly reduced by the "plancha" (OR 0.7, 95% CI 0.50-0.97). However, no significant effects on lung function were found after 12–18 months.[55]

The efforts to reduce the exposure or to introduce new energy technologies should take into account, the impact from interventions in the terms of dose-response relationships with health effects.[56] A study performed in Kenya indicates that, although improved woodstoves substantially reduce exposure, in many cases they offer smaller health benefits than a transition to charcoal, which can reduce the exposure to very low levels.[14] It is commonly suggested that biomass fuel should be replaced by fossil fuel, as pollution levels are believed to be higher with biomass fuel. However, in Bangladesh, the use of fossil fuels instead of biomass fuel did not necessarily improve the children's health.[27]

Smoke-free policies decrease ETS exposure by 80 to 90% in high-exposure settings. About 50% of countries in the world have at least minimal tobacco control policies in public places, but only 9% include also bars and restaurants, and 65 countries have no smoke-free policies on a national level. Even if the total global population covered by comprehensive smoke-free laws increased from 3.1% in 2007 to 5.4% in 2008 (due to new policies adopted in Colombia, Djibouti, Guatemala, Mauritius, Panama, Turkey and Zambia, in 2008), about two thirds of low-income countries (as well as two thirds of middle-income and half of high-income countries) have the lowest level of protection.

It is to point out that tobacco control is underfunded, especially in low-income countries, where the public spending for tobacco control is about $ 0.001 per capita "versus" about $1 in high-income countries.[4] Although it is impossible to directly ban passive smoking in private dwellings, a thorough health education campaign should be permanently implemented by health professionals, targeting primarily the parents of asthmatic children and relatives of cardiopulmonary patients.

Environmental Risk Factors for Respiratory Disease

Kalpana Balakrishnan

INTRODUCTION

The assessment of health risks from exposure to environmental air pollutants is a challenging task and involves integrating evidences from a broad range of disciplines including epidemiology, animal toxicology and human inhalation studies. The most comprehensive consolidation of this evidence was performed by the World Health Organization (WHO) as a part of the Comparative Risk Assessment exercise (WHO, 2002, 2004 and 2005) that not only estimated respiratory disease burdens but identified major contributing risk factors. Accordingly, 80 million people were estimated to have moderate-to-severe chronic obstructive pulmonary Disease (COPD). More than three million people died of COPD in 2005, which corresponds to 5% of all deaths globally. Although most of the information available on COPD prevalence, morbidity and mortality comes from high income countries, it is now known that almost 90% of COPD deaths occur in low- and middle-income countries. Acute respiratory infections (ARIs) account for about two million deaths each year and ranks first among causes of Disability-Adjusted Life Years (DALYs) lost in developing countries (94.6 million, 6.3% of total).

The most important environmental risk factors that contribute to this burden included exposures to indoor and outdoor air pollutants, allergens and occupational exposures (Table 101.1). These risk factors interact significantly with other lifestyle risk factors, including smoking, unhealthy diets, obesity and physical inactivity as well as genetic risk factors to modify attributable disease burdens. This chapter provides a brief description of the major environmental risk factors with respect to their sources, nature/chemical composition and prevalence of exposures among populations. Brief descriptions of epidemiological evidence of health effects and disease burdens are also provided (details of clinical manifestations and management may be found described in other chapters).

ENVIRONMENTAL RISK FACTORS

Outdoor Air Pollution

Sources and Composition

Outdoor air pollutants include two major categories viz those that are directly released into the atmosphere (primary air pollutants) and those that are formed after release in the atmosphere (secondary air pollutants). The physical state of pollutants (such as gaseous or particulate matter), the geographic location and distribution of sources determine levels of pollutions that may be found in the local, urban, regional and global scales.

Primary air pollutants include sulfur dioxide, oxides of nitrogen, carbon monoxide, volatile organic compounds, carbonaceous and non-carbonaceous primary particles. The main source of sulfur dioxide is the combustion of fuels containing sulfur. Fossil fuels and most notably coal and oil contain varying amounts of sulfur, according to their source but typically from 1% to 5%. On combustion, the sulfur in the fuel is converted to sulfur dioxide. In a process parallel to that of sulfur dioxide production during fuel combustion, nitrogen in fuels is also converted to oxides of nitrogen in the combustion process. The majority of nitrogen oxides

TABLE 101.1: Disability-adjusted life years (DALYs) (in millions) attributable to various risk factors, by level of socioeconomic development and sex, 2000 across world regions

	High mortality developing country		*Low mortality developing country*		*Developed country*	
	Males	*Females*	*Males*	*Females*	*Males*	*Females*
Total DALYs	421 (% of total)	412 (% of total)	223 (% of total)	185 (% of total)	118 (% of total)	97 (% of total)
Tobacco	3.4	0.6	6.2	1.3	17.1	6.2
Indoor smoke form solid fuels	3.7	3.6	1.5	2.3	0.2	0.3
Urban air pollution	0.4	0.3	1.0	0.9	0.6	0.5
Occupational airborne particulates	0.1	<0.1	0.87	0.1	0.4	0.1

(*Source:* WHO, 2002)

formed are emitted as nitric oxide, NO. A smaller amount, typically 5% of NO_x is emitted as primary nitrogen dioxide, NO_2, whilst the major proportion of atmospheric nitrogen dioxide is a secondary product of atmospheric chemistry. Carbon monoxide is formed by the incomplete combustion of carbon-containing fuels, e.g. combustion of fuel in vehicles. Volatile Organic Compounds (VOC) encompasses a very wide range of hydrocarbons, oxygenates, halogenates and other carbon compounds existing in the atmosphere in the vapor phase and are released upon evaporation of fuel as well as combustion. Particles are primarily generated by purely mechanical processes such as grinding or abrasion of surfaces and comprises of material in the solid or liquid phase suspended within the atmosphere. Such particles can be either primary or secondary and have a wide range of sizes. Newly formed secondary particles can be as small as 1 to 2 nanometers in diameter ($1\ nm = 10^{-9}\ m$) whilst coarse dust and sea salt particles can be as large as 100 micrometers ($1\ \mu m = 10^{-6}\ m$) or one tenth of a millimeter in diameter. However, the very large particles have a short atmospheric existence, tending to fall out rapidly through gravity and wind-driven impaction processes, and in practice there are few particles in the atmosphere exceeding 20 μm diameter except very close to sources of emission. Particles emitted from burning fossil fuels, coal and biomass may be emitted as carbonaceous particles that contain carbon, both in the elemental form and as organic compounds of low volatility or as non-carbonaceous primary particles (largely made of mineral material freed from a fuel such as coal in a combustion source and carried into the atmosphere with the flue gases). Particulate air pollutants have very diverse chemical composition and particle sizes which are highly dependent upon their source. Figure 101.1 illustrates the range of sizes (on a logarithmic scale) together with the ranges where certain important components are typically encountered.

Secondary air pollutants arise from chemical reactions of primary pollutants in the atmosphere, often involving natural components of the environment such as oxygen and water. Prominent secondary pollutants in the air include ozone, oxides of nitrogen and secondary particulate matter such as sulfates and nitrates.

Ambient Concentrations and Human Exposures

Exposures to air pollution are largely determined by the concentration of air pollutants in the environment where people spend their time and the amount of time they spend within them. Different methods of exposure assessment have been established that give qualitatively

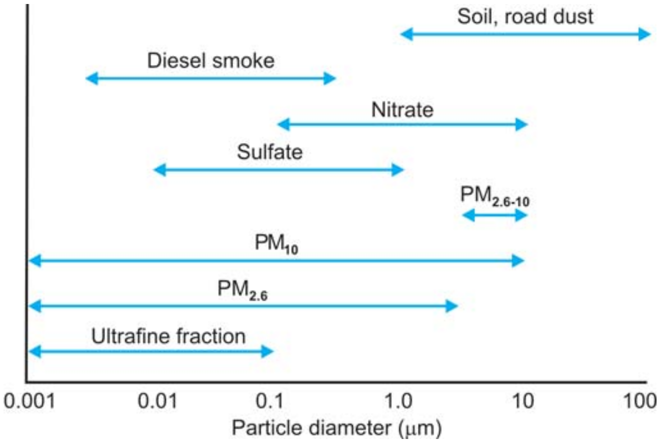

Fig. 101.1: Size range of air borne particles, showing the health related ultrafine, PM_2 and PM_{10} fractions, and the typical size range of some major components (*Source:* WHO, 2006)

different exposure estimates and differ in respect to precision, cost, feasibility and other factors. Among those methods are the fixed site measurements of ambient air pollutants, the modeled estimates of pollutant concentrations as well as personal measurements of exposure. Air quality measurements using fixed monitors that measure ambient concentrations of certain indicator pollutants (often termed criteria air pollutants) remain most widely used method to estimate human exposures. Such measurements during the last decade have shown air pollution problems in many major urban areas of the world. Some typical annual average concentrations of select criteria air pollutants across world cities shown in Figures 101.2 to 101.5, illustrate the regional differences in concentrations with rapidly developing countries of Asia facing the largest challenges.

Over the last decade, many cities have stepped efforts to provide a gridded network of air pollution monitors that operate throughout the year providing a more reliable estimate of population exposure together with

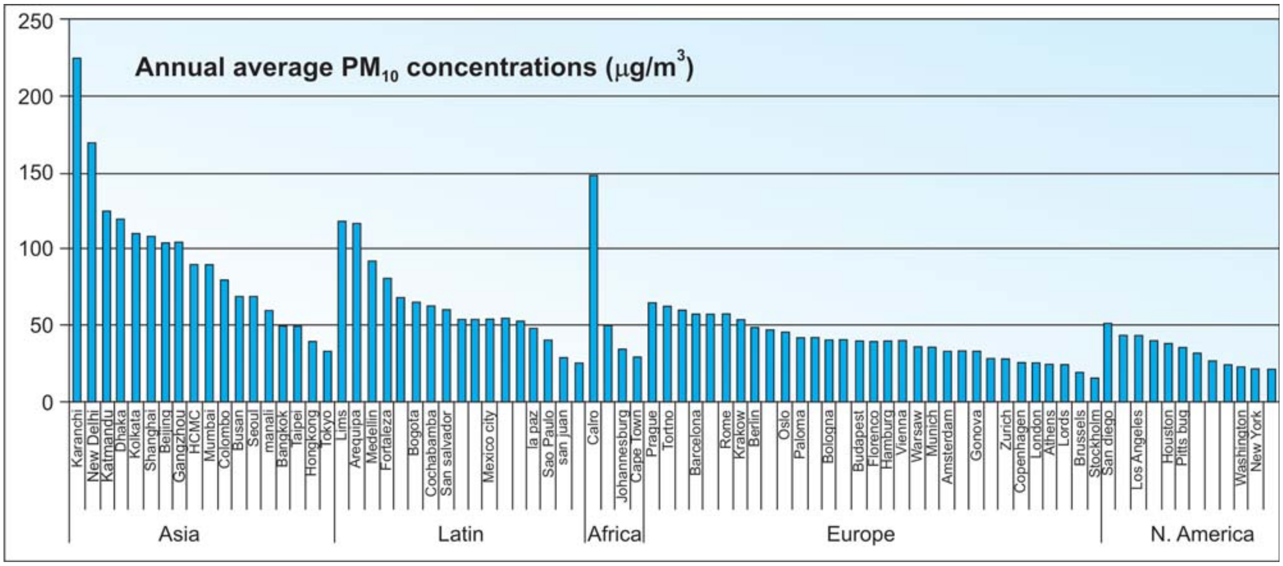

Fig. 101.2: Annual average PM_{10} concentrations observed in selected cities worldwide between 2000 to 2004 (*Source:* WHO, 2006)

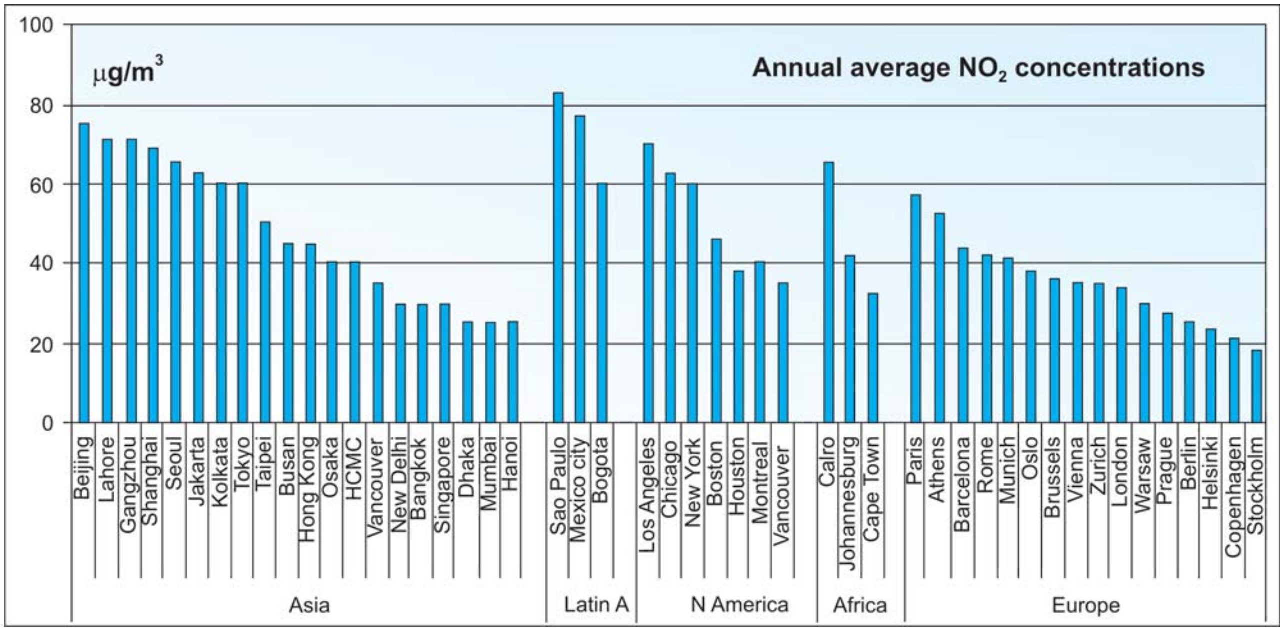

Fig. 101.5: Annual average NO_2 concentrations observed in selected cities worldwide between 2000-2004 (*Source:* WHO, 2006)

accompanying intra-city spatial/temporal differentials. The data has also become more easily accessible with many local pollution control agencies providing concurrent information on their websites. An example of data available through the Indian Central Pollution Control Board is provided in Figure 101.6.

Health Effects of Outdoor Air Pollution

There is now a wide body of literature available that documents health effects from criteria air pollutants in the urban outdoors. The earliest comprehensive consolidation of the evidence was provided by the first edition of the WHO Air Quality Guidelines for Europe

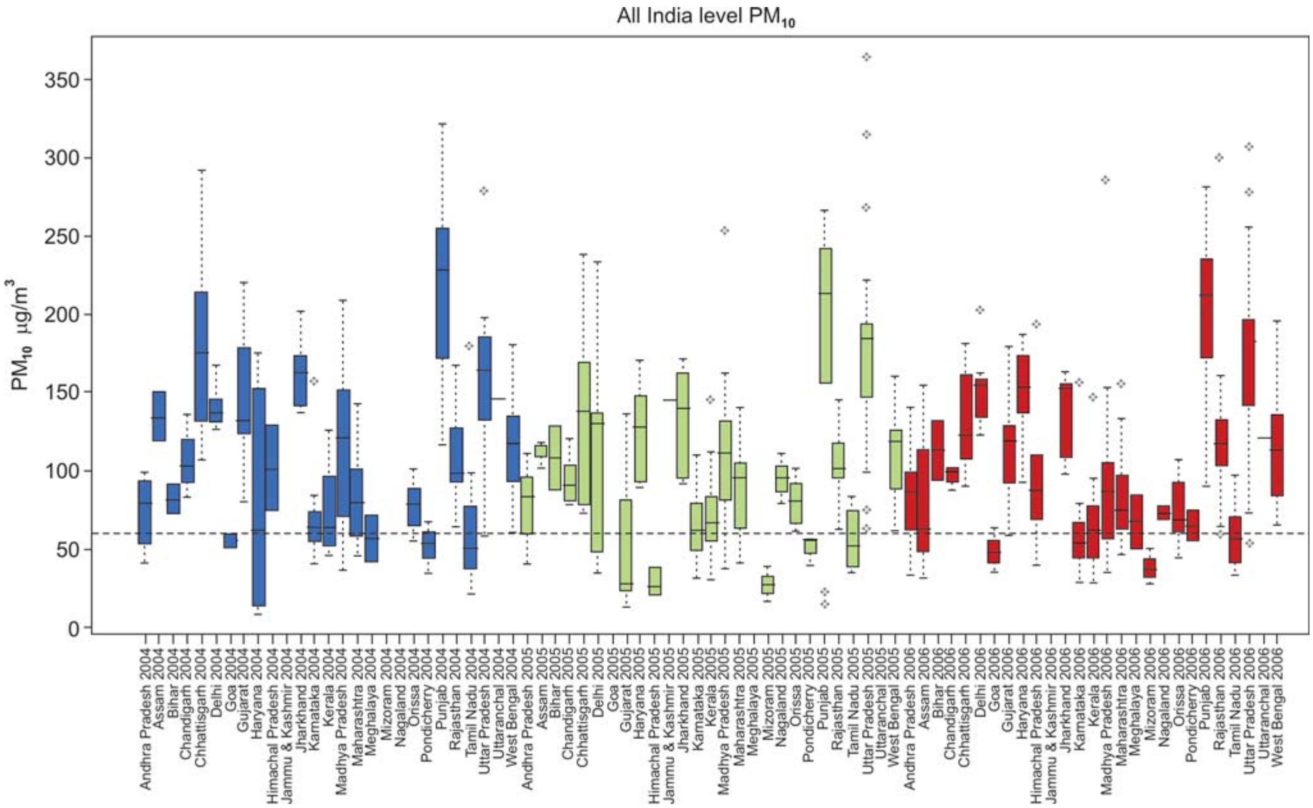

Fig. 101.6: Distribution of daily average concentrations of PM$_{10}$ across 126 cities in 25 states and 4 union territories in India over a 3 year period (2004-blue; 2005-green; 2006-red) shown as box-plots (*Source:* Central Pollution Control Board, Govt. of India)

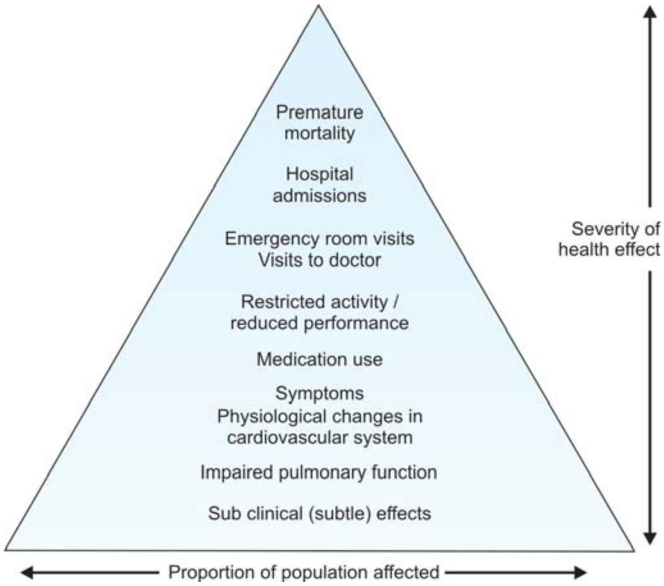
(WHO, 1987). This summarized scientific knowledge on the health hazards related to 28 most common air pollutants, providing a uniform basis for risk assessment of air pollution to the national authorities responsible for protecting populations from adverse effects of pollution. In the early 1990s, the growing body of knowledge allowed WHO to initiate the process of revising the Guidelines in 2000, summarizing risk characterization of 37 pollutants (AQG, 2000). The American Thoracic Society (ATS, 2000) provided the guidance on definitions of what constitute an adverse effect of outdoor air pollution (Fig. 101.7). While most of the literature generated in this period focused on respiratory and cardiovascular events attributed to short- and long-term exposures, a new generation of studies is suggesting that the occurrence of effects is not limited to these outcomes. An expanded list of outcomes reported in literature is listed in Table 101.2. The WHO lead “Comparative Risk Assessment” (WHO, 2002) pointed out that while largest burden of disease attributable to outdoor air pollution is borne by regions of the world besides Europe and North America, most studies that informed this estimation came from this region. Considerable uncertainties remained in extrapolating exposure—response relationships to regions where the exposure is often an order of magnitude higher. The newly formulated WHO Air Quality Guidelines (AQG, 2006) recognizing this wide disparity in exposure levels, has provided interim targets that all regions of the world should attempt to reach in the near–term with the guideline values serving as a benchmark, where minimal impacts may be expected to occur.

Indoor Air Pollution

Household Solid Fuel Combustion

Nature and sources: Nearly three billion people, mostly in the least developed and developing countries are estimated to rely on solid fuels such as biomass (wood, agricultural residues and animal dung), charcoal and coal for cooking and other household energy needs. Solid fuels in these households is often used in inefficient and poorly vented combustion devices that results in bulk of the fuel energy being emitted and wasted as toxic products of incomplete combustion. Further, their use in small and poorly ventilated kitchens in close proximity to household members, on a daily basis over many years often spanning entire life times, creates an exposure situation that is significantly detrimental to health of all family members, in particular for women and children who spend the largest fraction of time within or near the kitchen.



Premature mortality
Hospital admissions
Emergency room visits
Visits to doctor
Restricted activity / reduced performance
Medication use
Symptoms
Physiological changes in cardiovascular system
Impaired pulmonary function
Sub clinical (subtle) effects
Severity of health effect
Proportion of population affected

Fig. 101.7: Pyramid of health effects associated with air pollution (*Source:* ATS, 2000)

TABLE 101.2 Health effects attributed to outdoor air pollution

Effects attributed to short-term exposures

- Daily mortality
- Respiratory and cardiovascular hospital admissions
- Respiratory and cardiovascular emergency room visits
- Respiratory and cardiovascular primary care visits
- Use of respiratory and cardiovascular medications
- Days of restricted activities
- Work absenteeism
- School days missed
- Acute symptoms (wheezing, coughing, phlegm production, respiratory infections)
- Physiologic changes (e.g. lung function)

Effects attributed to long-term exposures

- Mortality due to cardiovascular and respiratory disease
- Chronic respiratory diseases incidence and prevalence (asthma, COPD, chronic pathological changes)
- Chronic changes in physiologic functions
- Lung cancer
- Chronic cardiovascular disease
- Intrauterine growth restriction (term low birth weight, intrauterine growth retardation, small for gestational age)

Source: Adapted from WHO, 2000b

Several demographic surveys conducted in developing countries, especially over the last decade, have started to collect information on household fuel use. According to a recent UNDP review (UNDP, 2009), some 129 countries have data available on fuel use including access to modern fuels and fuels used for cooking. India and China together account for nearly half the global population, that uses solid fuels for cooking (27 and 25% respectively), followed by sub-Saharan Africa. Wood is the predominant type of solid fuel used although in many surveys the distinction between wood, woodchips and agricultural residues is not clearly made. Although, among developing countries nearly 40% rely on modern fuel gas, which is uncommon among the least developed countries. Other fuel use is concentrated in certain countries, e.g. charcoal in sub-Saharan Africa, coal in China, dung in India, kerosene in Djibouti and electricity in South Africa.

Emissions from combustion of household fuels: Within communities, there exists a great deal of diversity in types and quantities of household fuels used. Further, the nature of devices deployed to burn these fuels and conditions of combustion (such as temperature, air flow, shape of the combustion chamber) have major implications for the specific nature of emissions within a household. Under ideal conditions complete combustion of carbon would produce only carbondioxide and water. However, virtually all configurations of solid fuel use emit substantial quantities of Products of Incomplete Combustion (PICs) as conditions for efficient combustion of these fuels are difficult to achieve in typical household stoves. These include respirable particulate matter, gases such as carbon monoxide and nitrogen-dioxide, organic compounds including saturated hydrocarbons, polycyclic aromatic hydrocarbons including benzo(a)pyrene, alcohols, phenols, quinones/semi-quinones and chlorinated acids such as methylene chloride and dioxins. Combustion of coal in addition to the above pollutants may release oxides of sulfur and heavy metal contaminants including arsenic and fluorine. On an average, a typical solid fuel stove converts 6 to 20% of the fuel carbon into toxic substances. At least 28 pollutants have been shown to be toxic in animal studies and some 14 carcinogenic compounds, six cilia-toxic and mucus coagulating agents and 4- co-carcinogenic or cancer-promoting agents have been identified (Table 101.3).

In a recently concluded assessment by IARC, indoor emissions from household combustion of coal has been classified as being "carcinogenic to humans" (Group 1 carcinogen based on sufficient human and experimental evidence) while indoor emissions from household combustion of biomass fuel (mainly wood) has been classified as "probably carcinogenic to humans" (Group 2A carcinogen on the basis of limited evidence of carcinogenicity of biomass combustion emissions (mainly from wood) in humans and experimental animals; sufficient evidence of carcinogenicity of wood-smoke extracts in experimental animals; and strong evidence of mutagenicity) (Straif et al, 2007).

Exposures to health damaging pollutants from combustion of household fuels: Well over a hundred studies over the last two decades have assessed levels of indoor air pollutants in households using solid fuels. The methods employed range from collection of questionnaire based information to quantitative measurements of household level exposures. A global database that documents results from these measurements across some 70 studies from developing countries of Asia, Latin America, Africa and China (if reported in English) has been available as a WHO IAP database (WHO, 2005). Although a great majority of studies have performed single pollutant measurements on a cross sectional sample of households, select studies have made important contributions to examining temporal, spatial or multi-pollutant patterns, in addition to day-to-day or seasonal variability in concentrations and exposures (Saksena et al, 1992; Balakrishnan et al, 2002; Ezzati et al, 2000; Gongli, 2004). A few have also developed models to examine the differential contributions of household level determinants and validate the use of simpler household level indicators (that are relatively easy to collect) as a proxy for household level exposures (Balakrishnan, 2004; Bruce, 2004). The 2005 version of WHO Global IAP database is now being updated to serve as a background for the revised burden of disease assessments for solid fuel use. To date, data from nearly 107 studies has been abstracted in this updated database and provides information on measured concentrations of indoor air pollutants related to solid fuel use from around 30 countries spread over all WHO regions (Balakrishnan et al, 2009).

Particulate matter of various size fractions has been measured, most often followed by carbon monoxide. Other air toxics have seldom been reported. While earlier studies measured Total Suspended Particulate (TSP) matter over short sampling durations during cooking, many recent studies report results of PM_{10} or $PM_{2.5}$ over 24 hour periods. All solid fuel using households experience concentrations 2 to 5 folds (upto 10 folds) higher than available 24 hour WHO Air Quality Guidelines (AQG) for PM_{10} and $PM_{2.5}$. Even gas using households in rural areas barely meet the AQG values presumably due a high background of outdoor air pollution resulting from venting/dispersion of solid fuel smoke from solid fuel using households. Figure 101.8

TABLE 101.3: Toxic pollutants from solid fuel combustion and potential for toxicity

Pollutant	*Known toxicological characteristics*
1. Particulates (PM_{10}, $PM_{2.5}$)	Bronchial irritation, inflammation increased reactivity, reduced mucociliary clearance, reduced macrophage response
2. Carbon monoxide	Reduced oxygen delivery to tissues due to formation of carboxy-hemoglobin
3. Nitrogen dioxide (relatively small amounts from low temperature combustion)	Bronchial reactivity, increased susceptibility to bacterial and viral lung infections
4. Sulfur dioxide (relatively small amount from most biofuels)	Bronchial reactivity (other toxic end points common to particulate fractions)
5. Organic air pollutants Formaldehyde 1,3 butadiene Benzene Acetaldehyde Phenols Pyrene Benzopyrene Benzo(a)pyrene Dibenzopyrenes Dibenzocarbazoles Cresols	Carcinogenicity Co-carcinogenicity Mucus coagulation, cilia toxicity Increased allergic sensitization Increased airway reactivity

shows the global distribution of solid fuel use while Figure 101.9 and Table 101.4 show the distribution of reported mean (arithmetic) values of particulate matter across various types of fuels in rural/urban studies (available in the global IAP database) that include all sampling durations and size fractions. As tabulated, the median values in liquid or gaseous fuel using households are observed to be 5 to 10 fold lower than what is reported in solid fuel using households. When compared in nested paired measurements, the levels in gaseous fuel using households is often 10 to 20 fold lower than experienced in corresponding solid fuel using households. Peak values in dung and coal using households have occasionally been observed to be 100 fold higher than corresponding gas using households.

Health effects and disease burden attributable to use of solid fuels: Evidence for health effects associated with exposure to smoke from combustion of biomass fuels was provided initially by studies on outdoor air pollution as well as by studies dealing with exposure to environmental tobacco smoke. Criteria documents for outdoor air pollutants published by the USEPA (USEPA, 1997) for example detail the effects of many components also found in wood smoke including particulate matter, carbon monoxide, oxides of sulfur and nitrogen, and polycyclic aromatic hydrocarbons.

Considerable scientific understanding now exists about aerodynamic properties of the particles that govern their penetration and deposition in the respiratory tract. The health effects of particles deposited in the airway depend on the defense mechanisms of the lung such as aerodynamic filtration, mucociliary clearance and in situ detoxification. Since most particulate matter in biomass fuel smoke is less than 3 µm in diameter, it is likely to reach the deepest portions of the respiratory tract and alter defense mechanisms. Several biomass fuel combustion products may also impair the mucociliary activity and reduce the clearance capacity of the lung resulting in increased residence time of inhaled particles, including

TABLE 101.4: Distribution of reported particulate matter concentrations in solid fuel using households (form studies available in the Global IAP database)

Type of fuel	*Mean*	*Median*	*SD*
Wood	2097.42	858.00	3892.85
Dung	7755.93	2619.00	11999.90
Charcoal	3926.11	1190.00	8395.52
Coal	820.20	533.00	579.43

Fuel unspecified	537.10	298.00	565.68
Kerosene	269.94	100.00	422.10
LPG/ Methane /Electricity	316.01	139.00	371.08
Mixed Liquid/ Gaseous fuel	375.75	397.67	148.61
Total	1408.90	500.00	3869.69

microorganisms. In situ detoxification, the main mechanism of defense in the deepest non-ciliated portions of the lung may also be compromised by exposure to components of biomass fuel smoke (Demarest, 1997).

Some of the earliest epidemiological evidences linking indoor air pollution from biomass combustion with respiratory health came from studies carried out in Nepal and India in the mid-1980s. Since then there have been a number of new studies, especially on women who cook with these fuels and young children. While a rigorous epidemiological framework that uses all criteria for establishing causality (such as the use of Bradford Hill's criteria) cannot be created from available studies, strong associations have been reported for a select set of health outcomes. These outcomes were used by WHO to prepare the first burden of disease estimates attributable to the household use of solid fuels in 2000. Since limited quantitative exposure estimates are available across multiple world regions (especially in developing countries where such exposures predominate), it was not possible to use a conventional exposure–response approach for these calculations. Instead, reported use of solid fuels was used as an indicator to stratify households as exposed versus not exposed in health studies. The odds ratios computed from these studies were then applied at a national/regional level where routinely collected demographic surveys provided fuel use information to allow burden of disease estimates (wherever fuel use information was not available it was modeled using econometric information).

For computing disease burdens associated with solid fuel use, estimates of relative risk obtained from epidemiological studies have been combined in meta-analyses for the three disease end-points for which there is strong evidence of an association with use of solid fuels viz. Acute Lower Respiratory Infection (ALRI) in children aged less than 5 years, COPD and lung cancer (only for use of coal). The WHO led CRA exercise estimates that more than 1.6 million deaths and over 38.5 million DALYs were attributable to indoor smoke from solid fuels in 2000 (Table 101.5). Cooking with solid fuels is thus responsible for a significant proportion, about 3%, of the global burden of disease. These risks are comparable to risks from tobacco and only exceeded by malnutrition (16%), unsafe water and sanitation (9%) and unsafe sex (4%).

Allergens in the Indoor Environment

Nature and sources: Allergens in built environments pertain mainly to microbial pollution involving hundreds of species of bacteria and fungi as well as protozoans and dust mites that grow when sufficient moisture is available. These agents are responsible for a large variety of respiratory symptoms, allergies and immunological reactions and have also been associated with asthma. They may be transported into buildings through active and passive ventilation or through contact with materials or clothing. They are found ubiquitously in all indoor environments including those without moisture but growth conditions become favorable only in the presence of water and nutrients (such as human scales for dust mites, plant, animal and other organic matter for fungi and bacteria) that abound indoors and especially in poorly ventilated moist spaces.

Classes of allergens produces by these organisms include proteases (such as Derp I and II produced by dust mites), enzymatic glycopeptides (such as those produced by IgG and IgE inducing fungi), endotoxins

(produced by gram-negative bacteria), fungal glucans, mycotoxins and volatile organics (produced by some fungi). Dampness and inadequate ventilation also favor the growth of bacteria and promote survival of viruses that are responsible for a range of respiratory infections.

Human exposures: The assessment of human exposure to allergens has been limited by the lack of routine monitoring methods to quantify allergen loads. While dampness is the most commonly used indicator of exposure, there is considerable variation and subjectivity on how dampness could be related to concentrations of microbes. There are many distinct challenges in assessment of indoor concentrations of microorganisms as well. Levels at which microorganisms may become hazardous may vary by several orders of magnitude between pathogenic and non-pathogenic species. Sampling inactivates many sensitive organisms while others such as spores are relatively robust. Sensitivity and specificity of methods to identify and count microbes are not uniform across species. Consequently, widely different concentrations have been reported even while using well-established methods (e.g. the *Limulus* amebocyte lysate assay for measuring bacterial endotoxins). Despite these limitations, culture and non-culture based analytical methods have been used in conjunction with active or passive to assess bioaerosol loads in many indoor environments. Most of such assessments have shown concentrations to be several folds higher in damp indoor spaces as compared to well ventilated dry indoor environments.

Health effects: In a recent assessment conducted by WHO to develop guidelines for indoor air quality related to dampness (WHO, 2009), reviews were performed to evaluate the epidemiological, toxicological and clinical evidence for association of dampness with respiratory ill-health. Although exposures to microbial agents have been quantified in some studies, these data were found to be too sparse to allow their use in health effects studies with the exception of select clinical studies. Most health effects have thus been observed in relation to prevalence of dampness. Key results of the meta-analyses of epidemiological studies are summarized in Table 101.6. In addition, the WHO review also provides details of studies to estimate the strength of toxicological and clinical evidence. These are summarized in Table 101.7.

Air Pollutants in the Occupational Environment

Several categories of air pollutants in the occupational environment have been well known and are well recognized to be causative agents for a wide range of respiratory health impairments ranging from respiratory symptoms, COPD and fibrotic lung diseases to lung cancer and asthma. These include airborne particulates in the form of mineral/organic dusts and fibers as well as occupational carcinogens such as solvents.

Well established guidelines for exposure assessment and medical surveillance are widely available through the numerous local and international regulations and publications of agencies such as the WHO, International Labor Organization and National Institute for Occupational Safety and Health (USA). These include agents such as asbestos, silica, cotton dust, heavy metals and volatile organic compounds. To reproduce such widely available information for agents would be redundant and instead descriptions of some newly emerging concerns are provided.

Ever-diagnosed asthma	All	8	1.37 (1.23-1.53)	33
Asthma development	All	4	1.34 (0.86-2.10)	30

TABLE 101.7: Strength of evidence for various health outcomes related to dampness (as an indicator of indoor microbial contamination), (WHO, 2009)

Strength of Evidence		*Health Effects*
Sufficient	Epidemiological	Asthma development, asthma exacerbation, current asthma, respiratory infections (except otitis media), upper respiratory tract symptoms,cough, wheeze and dyspnea
	Clinical	Hypersensitivity pneumonitis, allergic alveolitis and mould infections in susceptible individuals and inhalation fevers
Suggestive	Epidemiological	Allergic Rhinitis and Bronchitis
	Toxicological	Inflammation, cytotoxicity, immunosuppression
Inadequate		Lung function, allergy, atopy

Some examples of newly recognized occupational lung disease include flock worker's lung, hypersensitivity pneumonitis associated with biocontaminated synthetic metal working fluids, Severe Acute Respiratory Syndrome (SARS), asthma associated with 3-Amino-5-Mercapto-1,2,4-Triazole (AMT) in herbicide manufacture and bronchiolitis obliterans from flavoring chemicals. Nano-materials represent a particularly challenging class of occupational respiratory hazards as little is known about their disposition in the body following exposures. Table 101.8 provides a listing of some newly recognized respiratory hazards in the occupational environment and associated clinical conditions. While the occupational etiology for these risk factors have been established on the basis of a detailed history of exposure, little is known about the quantitative exposure levels or the mechanisms underlying disease causation. A general description of the exposure situations and clinical conditions are therefore provided for selected agents.

Bronchiolitis obliterans linked to the small-molecular-weight chemical diacetyl is frequently referred to as "popcorn lung disease" as the first outbreak of cases were noted among manufacturing workers in a popcorn plant where diacetyl was being used to produce butter-like flavoring. "Flock-worker's lung" represents another emerging occupational respiratory disease reported amongst workers dealing with flock made of nylon, polyethylene, polypropylene and rayon. Short length synthetic fibers produced by rotary or guillotine blades and cleaning operations are known to be most prevalent exposure circumstance. The use of a series of commercial products with waterproofing components (Table 101.8) has been associated with outbreaks of a new syndrome of acute lung injury, ranging from a mild, nonspecific chemical pneumonitis to full-blown ARDS with diffuse alveolar damage. The unifying characteristic of these products is the presence of fluoropolymers that are not present as

TABLE 101.8: Newly emerging occupational respiratory conditions and associated risk factors/exposures

Disease or Syndrome	*Emerging Exposure or Newly Recognized Risk Factor*
Bronchiolitis obliterans	Flavoring industry chemical exposure (diacetyl)
Bronchiolitis obliterans	Boat building (fiberglass coating materials)
Lymphocytic bronchiolitis	Flock fibers (nylon, polyethylene, polypropylene,rayon)
Pneumonitis, acute lung injury	Waterproofing materials (various consumer applications)
Alveolitis, pulmonary fibrosis	Flat panel display production (indium tin oxide)
Dendriform pulmonary ossification	Rare earth pneumoconiosis (cerium oxide)
Pulmonary fibrosis, pleural effusion	Heavy industrial exposure to polyacrylate nanoparticle aerosols
Anthracofibrosis	Mining, dusty trades (heavy mineral dust exposure)
Extrinsic allergic alveolitis	Animal feed industry (phytase enzymes)
Asthma	Point of sale computer terminal use (thermal paper)
Asthma	Biochemical synthesis (peptide couplers)
Asthma	Orthopedic casting (isocyanates)
Asthma	Nail salon work (methacrylates)
Silicosis	Sandblasting jeans (silica)
Respiratory bronchitis - interstitial lung disease	Hospitality work (secondhand smoke)
Idiopathic pulmonary fibrosis	Wood and metal working (wood, metal dusts)
Sarcoidosis	Building debris clean up (mixed dust)

propellants but as an ingredient that provides the key waterproofing characteristic of the application in question.

Exposure to indium tin oxide, a sintered metal alloy that is a key component used in the manufacturing of liquid crystal or plasma flat-panel display units (Table 101.1), has been linked to alveolitis and pulmonary fibrosis among production workers. Although, to date, this novel form of pneumoconiosis has been reported only from Japan, where the industry is concentrated, it is likely that additional cases are occurring wherever this alloy is heavily used in manufacturing or where exposure may occur through recycling.

Recording of detailed exposure histories together with medical surveillance in the workplace has allowed the recognition of new risk factors for established diseases (as in the case of newly recognized agents for occupational asthma such as animal feeds, commercial cleaning products, thermal paper, etc.) or new exposure situations for established cause of disease (such as isocyanates in health care, silica in sandblasting of denim jeans and asbestos in ship breaking).

In summary, an effective surveillance strategy at the workplace is critical to manage well known risks and recognize newly emerging risks. This will allow prevention of many conditions that were hitherto labeled as "idiopathic" for need of routine data on health and exposures at the workplace.

CONCLUSION

The preceding paragraphs provide an overview of the important environmental risk factors that contribute significantly to the prevalence and burden of respiratory disease. With an exception of high-level occupational exposures that may trigger outbreaks or episodic illness that may be relatively easily recognized through company level medical surveillance, the other population level risk factors in the outdoor and indoor environment contributing may not merit much attention in routine medical practice. Lack of recognition and awareness on the merging body of scientific evidence for exposures and related health impacts often poses significant challenges for public health, as professionals vested with the responsibility of intervention do not perceive the "risks." In developing countries with large populations such as India, there is a tremendous need for conduct of epidemiological studies that may generate the much needed "evidence for policy" at the local levels. Few, if any, longitudinal studies that examine multiple risk factors and their interactions in contributing to health impacts for the general population as well as development, progress and management of clinical conditions, are available in settings where exposures predominate.

Inclusion of the results of important recent scientific research related to the recognition and evaluation of environmental risk factors for respiratory disease in routine curriculum of medical and public health programs is necessary to build capacities to address these risks in the near term. As with most disease conditions, prevention is far more cost-effective than management but is particularly so with the risk factors in the "modifiable environment." It is hoped that information provided in this chapter has made a small but significant incremental step in that direction.

Climate Change and Lung Disease—With Special Focus on Developing Countries

Kin Bong Hubert Lam, Jon G Ayres

CLIMATE CHANGE: AN INTRODUCTION

The Earth's climate is a system determined by complex interactions between solar radiation, atmosphere (temperature, precipitation, humidity, atmospheric pressure and wind), lithosphere (land masses and tectonic activity), hydrosphere (water bodies) and biosphere (living beings). Climate is thus highly dynamic, influenced by both internal components and external factors (known as "forcings") and evolves over time. As a result, it is often described by "statistical description in terms of the mean and variability" of its meteorological elements (primarily temperature, precipitation and wind) over a period of time.[1] Over the last decade or so, global temperatures have been rising and increasing concern has been expressed about the likely impact of this climate change on the Earth, in general and on health, in particular.

While by definition natural phenomena such as solar variations and volcanic eruptions can cause fluctuations in climate, there is an increasing body of evidence which has suggested that anthropogenic activity, since the industrial revolution, has been the key driver of climate change. An increasing worldwide population and economic development have resulted in greater demands on energy supply, transport, agriculture and industry, which ultimately have led to increased emissions of carbon dioxide (CO_2) from fossil fuel combustion and other greenhouse gases (GHG) including halogen-containing gases, methane (CH_4), nitrous oxide (N_2O) and tropospheric ozone. For instance, atmospheric CO_2 levels at Mauna Loa, Hawaii rose from 316 parts per million by volume (ppmv) in March 1958 to 389 ppmv in January 2010,[2] while historical data derived from ice cores suggest that preindustrial atmospheric CO_2 was probably in the range 275 to 284 ppmv.[3] At the same time, between 1906 and 2005 global surface temperatures have increased by about 0.74°C (±0.18°C).[1] Although this warming is not globally uniform, the trend is reconciled by observed changes in other components of the climate system, such that the increase in atmospheric concentration of GHG has been implicated as the predominant forcing of climate change and is otherwise unlikely to be fully explained by confounders.

Increase in the mean surface air temperature on a global scale is just one of the manifestations of climate change. Consistent with the overall warming trend, the number of extremely hot days and warm nights has been increasing since the 1950s,[4] and in recent years heat waves have been more common worldwide. Severe heat waves were recorded in Europe in 2003 and 2006, and a large part of Asia was affected in 2007; resulting in marked increases in mortality. Climate change also results in alterations in precipitation patterns. Compounded by oscillations in climate pattern such as El Niño, climate change is regarded as being responsible for more frequent and intensive floods and droughts, severely affecting the developing countries where water supply, irrigation and sewage infrastructure is not very well established.

Climate change is a challenge faced by all living beings and is not restricted to a single geographical region, posing serious threats to both developed (coincidently mostly situated in the temperate latitudes) and developing countries (often within the intertropical zone), although it is expected that the developing countries, particularly those who live in poverty, will be disproportionately more affected by climate change.

FUTURE PROJECTIONS OF CLIMATE CHANGE

It is generally agreed that global temperatures will continue to rise for decades to come, largely due to GHG produced by human activities. The Intergovernmental Panel on Climate Change (IPCC) forecasts an increase of 1.1°C to 6.4°C in the global mean surface air temperature over the 21st century.[5] However, the extent of effects on individual regions will vary by latitude, altitude and proximity to water bodies as well as by external factors such as the level of human activities, and development (e.g. deforestation, urbanization). For example, between 1961 and 2000, an increase in the number of warm spells over southern and western Africa was recorded,[6] while in eastern Africa decreasing trends in temperature were observed from weather stations close to the coast or to major inland lakes.[7] Similarly, different precipitation patterns exist in different regions, as a result it is difficult to assess or to project the exact impact of climate change in individual regions.

In certain regions, warmer temperatures with increased precipitation may bring short and medium-term benefits (e.g. in the agricultural industry). However, when taken as a whole, the damage caused by climate change is likely to outweigh the benefits and to increase over time.[8] Decreased rainfall in northern Africa and much of the south is projected,[9] leading to increased water stress and reduced agricultural production. Likewise, a decrease in precipitation in central Asia is expected, accompanied by an increase in the frequency of very dry spring, summer and autumn seasons. In contrast, it is likely that there will be an increased risk of flooding along the coasts of South and Southeast Asia due to the rise in sea level. In south and south-western Latin America, the retreat of glaciers in the Andes and reduced precipitation will probably reduce fresh water availability. In North America, increased frequency, intensity and duration of heat waves is projected and storms are likely to be more often in the coastal areas. Floods in maritime and inland areas are projected to occur more often in Europe. There will almost certainly be less number of cold days, but accompanied by prolonged episodes of hot weather. Climate models suggest there would be more heat waves and greater intensity of droughts in Australia. Climate change will also result in major changes in vegetation and hence ecosystems such as the likely replacement of Amazonian tropical rainforest by savannas.

IMPACT OF CLIMATE CHANGE ON HEALTH

Human health is determined by complex interactions between an individual and the environment in which the local climate plays an important role. Extreme temperatures on their own can cause morbidity (e.g. heat stroke and frostbite) and mortality. Climate-associated disturbances in ecosystems and environment can lead to changes in the spatial and seasonal distribution of disease vectors and allergens, which in turn cause an impact on the incidence and prevalence of communicable diseases and allergy. Indirectly, climate change, through the action of extreme events such as droughts and floods, can incur injury and fatality thereby causing implications in food production and settlement. The burden on cardiorespiratory and gastrointestinal morbidity due to deteriorating air and water quality is expected to increase. The extent of the effect of climate change on human health varies by region, by vulnerability of population groups and individuals, and by the ability of the society to adapt to the change.

CLIMATE CHANGE AND LUNG DISEASE

While the health impact of climate change is nonspecific, its effect on respiratory health warrants special attention, as the respiratory system is inevitably susceptible to changes in atmospheric parameters. Several critical components of climate change (Table 102.1) could influence lung diseases, notably asthma, rhinosinusitis, chronic obstructive pulmonary disease (COPD), pulmonary tuberculosis and respiratory tract infections. The impact varies in extent and severity according to the susceptibility of populations and individuals; with areas of greater poverty with less-well-developed or limited access to medical services suffering more. This will include migrating populations and areas where population growth is greatest.

Extreme Temperature Events

The relationship between health and temperature follows a U-shaped curve, with excess impacts increasing with both colder and hotter temperatures. Heat waves and cold "snaps" are the prime examples of extreme temperature events. For heat waves, the impact is likely to be greater in temperate regions due to poorer preparation for hot weather in these areas. But the

TABLE 102.1: Climate change components which could influence lung disease

- Extreme temperature events
- Changes in air quality
- Precipitation patterns
- Allergen disposition
- Vector transmission

developing countries, despite the fact that some of them lie in tropical regions, could be as vulnerable because of inferior medical services. Populations with limited adaptive capacity, such as the elderly and patients with COPD or other chronic conditions are likely to be particularly susceptible.

Western Europe experienced a large scale heat wave in the summer of 2003, with maximum temperatures rising to over 40°C in many places. It was estimated that some 22,000 excess deaths resulted in England and Wales, France, Italy and Portugal during and immediately after the heat wave.[10] In France during the period from August 1st to 20th, respiratory mortality increased by 90% (95% CI 80% to 100%) overall. This effect increased with age, mortality increasing by 50% (30% to 70%) for those aged 45 to 74 years; and 110% (100% to 120%) for those aged 75 or older (Fig. 102.1).[11] Many parts of Asia suffered similarly. In Shanghai alone, it was estimated that mortality went up by 13% (95% CI 6 to 20%), with respiratory deaths increasing by 23% (95% CI 2 to 48%) during the heat wave compared to other summer days in the same year.(12)

But these adverse effects are not simply seen with overt heat waves, there being a general relationship between health outcomes and temperature. This was first quantified by Farr in the UK in the first part of the 19th century who showed the degree to which mortality increased for each degree in temperature fall in the winter months *(Macfarlane A. Daily mortality and environment in English conurbations. Air pollution, low temperature, and influenza in Greater London. Br J Prev Soc Med. 1977;31(1):54-61)*. More recently, data from New York City suggested that there is a 2.7% (95% CI 1.3% to 4.2%) increase in risk for respiratory admission on the same day for every 1°C above a calculated temperature threshold of 28.9°C.[13] Similar findings were reported in a study of 12 European cities, which estimated a 2.1% (95% CI 0.6% to 3.6%) increase in respiratory admissions in Mediterranean cities and 1.2% (0.1% to 2.2%) in the north-continental cities for a 1°C rise in maximum

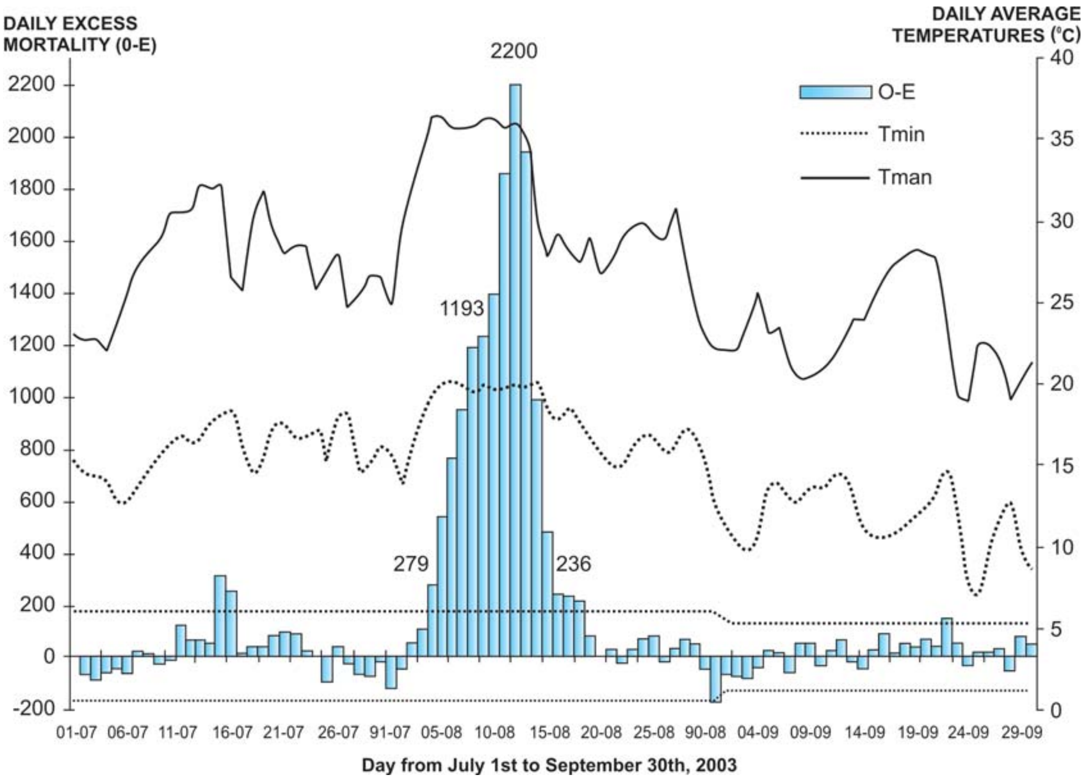

Fig. 102.1: Number of excess deaths and average daily maximum (Tmax) and minimum (Tmin) temperatures during the 2003 heat wave in France

The x axis shows the 92 days from July 1st to September 30th 2003. The histogram shows the numerical values of the daily excess mortality for August 4, 8, 12 and 16.

The dotted horizontal lines show the limits of the 95% fluctuation intervals of the daily number of deaths.

Adapted from Reference 11.

apparent temperature above the city-specific threshold,[14] with an effect on respiratory mortality appearing to be larger. A related meta-analysis based on mortality data from 15 cities indicated a 6.7% (2.4% to 11.3%) increase in respiratory mortality in the Mediterranean region and a 6.1% (2.5% to 11.1%) increase in the north.[15] In developing countries, particularly in rural areas, much of the hospitalizations and excess deaths during the heat wave period are probably due to heatstroke for which data and therefore predictions of respiratory deaths, are less reliable.

Air Pollution

Ground level air quality is highly dependent on weather conditions, which dictate the accumulation and dispersion of air pollutants. Human activities generate large quantities of pollutants, comprising mainly particulate matter (PM), sulphur dioxide (SO_2), nitrogen oxides (NO_x), carbon monoxide (CO), CO_2 and volatile organic compounds (VOCs). Depending on the country or area, the sources of these pollutants vary but the two main contributors are vehicle emissions and industrial emissions.

Ozone

The pollutant of maximum concern in the context of climate change is ozone because of its atmospheric chemistry. Under suitable weather conditions, NO_x, CO and VOCs will react with ultraviolet radiation to form ozone, a primary constituent of urban smog and a potent GHG in its own right. The rate of photochemical reactions in which ozone is formed is determined by temperature, solar radiation and atmospheric moisture with precursor emission levels.[16] Some of these factors are expected to be altered due to climate change and as current concentrations of tropospheric ozone are on the rise,[17,18] it is predicted that levels will continue to increase although wide regional differences are expected.[19]

In developed countries, exposure to high levels of ozone has been shown to be associated with an increase in respiratory morbidity and mortality (Table 102.2). At present, ozone is regarded as a non-threshold pollutant (i.e. at a population level effects from ozone occur linearly down towards zero) but if thresholds for some outcomes are identified this will have a major impact on calculations of health burden from any rise in ozone levels. There is some evidence to suggest that repeated exposure to ozone induces tolerance. However it is unclear to what extent this would be possible with a situation of gradually increasing levels day-on-day.

TABLE 102.2: Respiratory morbidity from exposure to high ozone levels

- Reduced lung function[20]
- Exacerbation of chronic respiratory diseases[21]
- Increased hospital admissions for pneumonia, COPD, asthma, allergic rhinitis and other respiratory diseases, and with premature mortality as well as with cardiovascular disease.[22-26]

Particulate Matter

PM may be influenced by climate change as its formation is in part determined by temperature and humidity while effects on industrialisation and population migration will also influence levels. The extent to which levels of PM will increase in global terms is uncertain, however, as events secondary to climate change such as reduction of emissions in some areas (albeit with increases in others), windblown dust as a result of deforestation and desertification and higher frequency of forest and bush fires could affect levels in varying and unpredictable ways.

Evidence for the health impacts of PM is stronger than that for ozone. Long-term exposure to PM has been associated with increased prevalence of symptoms and reduced lung function in asthmatic children,[27] and higher mortality in adults, including lung cancer deaths.[28-30] Similarly, short-term increase in ambient PM levels have been related to increase in cardiopulmonary hospital admissions and mortality.[31-33] In Malaysia and Brazil, increase in the number and extent of forest fires was associated with increased outpatient visits for respiratory disease.[34] PM generated in this way can affect air quality in areas thousands of kilometers away,[35] but accurate prediction of such effects is difficult.

Other Pollutants

While highway infrastructure is not well established in developing countries, but their urban air quality could be worse than the developed countries with high rate of car ownership, the reason being a combination of the use of low quality fuel (both in automobiles and power stations), poorly maintained vehicles and the lack of emission control legislation and enforcement. Coal-fired power stations are common in many developing countries. The use of coal with high sulphur content and the absence of flue-gas desulphurisation mechanisms lead to the emission of SO_2, which is a cause of acidification of soil and water. SO_2 has a marked bronchoconstrictor effect in asthmatics and this susceptibility was used as a driver in the UK to establish their Air

Quality Standard for this gas as a short term (15 minute) value.[36] SO_2 exposure has been associated with both respiratory,[37] and cardiac,[38] admissions although separating out the effect of this gas from PM (which are so often closely correlated in terms of air concentrations) is difficult and may have resulted in either over or under-estimation of the true effect sizes. Nevertheless, as temperature continues to rise with climate change, air conditioning will become even more widespread, especially in tropical regions, in turn boosting energy demand and producing more GHG (primarily CO_2) and SO_2, further impacting on the environment and the climate.

The burning of solid fuel, primarily biomass, in households is very common in rural parts of many developing countries and it has been estimated that over half the world's population (over three billion) is exposed indoors to smoke from burning of wood, animal dung, crop residues or coal. As a result of the use of these often low quality fuels and the use of simple open fires or low efficiency stoves, burning of biomass fuels often gives rise to large quantities of carbon with various additional components. These exposures are associated with increased risk of acute lower respiratory infections notably in children and also an increased risk of COPD and for coal in particular, lung cancer in the longer term. These emissions also contribute to global warming (from their gaseous rather than particulate components),[39] and changes in the use of biomass fuels associated with migrating populations associated with desertification may increase the spread and maybe the extent of the amount of fuel burnt in this way. In addition, as the impact of climate change intensifies, it is highly likely that the economies of developing countries will be affected (e.g. crop failure, population re-settlement because of extreme weather events). Without international support, the pace in the reduction of biomass emissions or the switchover to alternative fuel will be inevitably be slowed down or reprioritized.

SYNERGY BETWEEN AIR POLLUTION AND TEMPERATURE

Given temperature is the determinant of the formation of both ozone and PM, it is not surprising that climate change alone can enhance the adverse effects of these pollutants even when their levels remain stable. There is some evidence suggesting a synergistic effect between ozone/PM and temperature, particularly during the warm season,[40-43] for both respiratory and cardiovascular impacts. More recently, experimental work confirms that the redox activity of PM is amplified by ozone,[44] raising the possibility of a three-way interaction between PM, ozone and temperature.

Extreme Precipitation

Climate change is likely to cause increased variability in precipitation, with both more extreme episodes of rain and prolonged periods of drought. In either case, human lives and properties are as vulnerable. Floods threaten those populations whose habitation is in low-lying plains and coastal regions, which may result in both temporary displacement of the affected population and potentially longer term population relocation. The lack of clean water and food compounded with poor sanitation in crowded temporary settlements is one of the major causes of communicable diseases outbreaks. For example, diarrhoea and respiratory infection were the leading causes of morbidity and mortality in Bangladesh in 1988 during and after a major flood in the Irrawaddy delta.[45]

After floodwaters recede, the affected population is likely to move back to their homes, at varying times after the initial episode. If return is immediate the dwellings, while habitable, are likely to remain damp and run the risk of mould outgrowth. Living and working in damp housing is known to cause respiratory symptoms such as cough and wheeze,[46-48] and is also associated with an increased risk of developing asthma. This has been observed in both the developed and developing world.[49-51] It is not completely clear whether this association is simply due to damp or is related to allergic sensitization following mould exposure[52] or may represent the effects of other potential exposures, such as endotoxin,[53] and mycotoxins,[54] but living in damp housing is clearly associated with increased respiratory morbidity.

Droughts, on the other hand, do not directly impact on lung diseases except by reducing nutritional status and therefore increasing the risk of respiratory infection. In addition, desertification and the subsequent dust storms brought about by extended dry weather are likely to cause acute effects on the population with preexisting respiratory conditions as well as attacks of acute bronchitis even in those with previously healthy lungs.[55-57]

Effects on Allergens and Allergic Responses

Climate change, particularly increase in temperature and CO_2 levels, along with changes in humidity, is likely to have effect on the spatial distribution and life cycles of many species of flora, and hence the onset and length of their pollen seasons.[58-60] Plant species that were originally alien to a particular region may establish themselves because of changing climate and environment, thus introducing new allergens into the area and increasing rates of sensitization. [61] It is unclear whether allergic responses such as allergic rhinitis and asthma incidence and exacerbations would increase in absolute terms, but as ozone potentiates the effects of allergen exposure,[62] the likely increase in ozone levels should, regardless of whether new flora are present in any given area, result in more symptoms and attacks in sensitized individuals.

Changes in Respiratory Infections

The combination of higher temperatures and increased precipitation is likely to produce breeding conditions favoring greater incidences of a number of vector- and water-borne infectious diseases and prolonging their transmission season. In some cases this may increase the risk of acute respiratory infections in individuals compromised by such conditions although in general, the frequency of respiratory infections with climate change may decrease as such infections are more common during winter months.[63] Nevertheless, climate change can also affect population behavior, making it difficult to predict both the direction and magnitude of any change in infection incidence. For example, population dislocation due to extreme weather events could result in overcrowding and deterioration in hygiene and living conditions which may lead to an increase in tuberculosis, particularly in regions where the condition is prevalent.

Deforestation and other changes in the natural habitats brought about by climate change can have a major impact on wildlife, driving them to settle in closer proximity to the mankind, in turn leading to more frequent human contact and increased likelihood of zoonosis (infectious disease transmitted from animals to humans). Prime examples include the recent emergence of avian influenza virus (H5N1) and severe acute respiratory syndrome (SARS) coronavirus in East Asia, which are found in migratory birds,[64,65] and bats,[66,67] respectively. It is also possible that the seasonal and geographical distribution and transmission of pathogens could be altered by climate change. While there is no evidence showing the direct causal link, it has been reported that human adaption to climate change could also influence risks of infection. For instance, the use of open containers to store water during droughts has been associated with the outbreaks of Chikungunya fever, a mosquito-borne viral disease in Kenya.[68] First discovered in and thought to be limited to Africa, Chikungunya virus has recently emerged in Asian countries in the Indian Ocean,[69] as well as in the more distant Italy.[70] Although rising temperature in South Asia was suggested to be a contributory factor for enhanced transmission,[71] it is unclear whether the same holds true for its emergence in Europe.

CONCLUSION

While it is generally accepted that climate change is a mainstream public concern, the full extent of the scale and the effects of its direct and indirect consequences are not clear and can only be estimated by means of projections based on currently available evidence. The geographical and socioeconomic differences and disparities between countries add further levels of uncertainty. If there is one thing that is certain about climate change, it is that predicting health impacts is difficult and at times impossible. As the mean surface air temperature continues to rise, it is highly likely to be accompanied by more frequent and more intense extreme weather events, causing major disruptions to society and economic activities, and loss of life.

In terms of the impact on respiratory health, climate change is likely to increase the morbidity and mortality burden among those who have existing chronic conditions such as COPD. It also alters the patterns of seasonality, transmission and geographical distributions of infectious and allergic diseases. As strategies are being formulated to minimize, the health-related burden of climate change, it needs to be emphasized that its effects are not bounded by national frontiers and attempts at both mitigation and adaptation are needed through international and local collaboration. It should be regarded as mandatory to incorporate the specific needs of each individual population as there exists substantial regional variations, in terms of the scale of local climate change, population vulnerability and the ability to mitigate and adapt. Researchers, policy-makers and other stakeholders need to work more closely together to translate the research findings and develop appropriate action plans to ensure the sustainability of mankind in our approach to climate change.

High Altitude Problems

Ajay Handa

INTRODUCTION

Ascent to altitude poses immense challenges on human body, including exposure to extremely low temperatures, low atmospheric pressures and hypoxia, which may lead to specific altitude related illnesses such as Acute Mountain Sickness (AMS), High Altitude Cerebral Edema (HACE) and High Altitude Pulmonary Edema (HAPE). These illnesses can be severe enough to compromise safety of travelers and if remain unrecognized may even prove to be fatal.

The occurrence of high altitude-related illnesses in those with pre-existing lung disease is of greater concern due to limited physiological reserve. However, there is scarcity of data regarding the risk of the development of altitude-related illnesses and the effect of high altitude on the underlying lung diseases. With changing lifestyle and increased spirit of adventure in the present era, more people with lung diseases are traveling to High Altitude Areas (HAA) for leisure and are therefore likely to develop these problems.[1]

Physical Changes with Altitude

The most significant change with altitude is decrease in barometric pressure with increasing altitude. This leads to lower inspired oxygen and thus lower alveolar oxygen partial pressure (P_AO_2) and arterial oxygen tension (P_aO_2) values. There is a reduction in air density and temperature with gain in altitude, this leads to greater insensible water losses through the respiratory tract. Air has less of house dust mite allergens with increasing altitude due to the low temperatures and reduced humidity. [2]

Pulmonary Adaptation to High Altitude

The various adaptive changes in the respiratory, cardiovascular and hematological systems, which allow the humans to survive in high altitude areas constitute "acclimatization". The main changes include compensatory increase in ventilation due to the decreased P_aO_2 called Hypoxic Ventilatory Response (HVR). There is an increased work of breathing and respiratory muscle oxygen consumption, thereby limiting exercise capacity at high altitude.[1]

Gas exchange in the alveolar capillaries is adversely affected by low P_AO_2 (reduced alveolar-capillary gradient) combined with a lower mixed venous oxygen levels, which delay alveolar-capillary equilibration.[3] These problems are aggravated during exercise due to increased cardiac output, shortened capillary transit time and greater venous oxygen desaturation leading to further arterial desaturation.[4]

Despite decrease in blood oxygen content, the delivery of oxygen to tissues is maintained by increased cardiac output and increased red cell mass (hypoxia induced erythropoietin secretion). Also, the hemoglobin-oxygen dissociation curve is shifted to right due to increased 2, 3 diphosphoglycerate production, which counteracts the hyperventilation induced respiratory alkalosis at high altitudes.[1]

The alveolar hypoxia triggers hypoxic pulmonary vasoconstriction (HPV) to maintain ventilation perfusion relationship and this causes a rise in pulmonary arterial pressure. This is important in the pathogenesis of HAPE and altitude related pulmonary hypertension.[5-7]

Most studies have shown a fall in vital capacity, an increase in TLC and residual volume at high altitudes.

The data regarding changes in the Forced Expiratory Volume in One Second (FEV_1) are conflicting. There is clear evidence that Peak Expiratory Flow (PEF) is increased and airways resistance is reduced due to the decreased air density at high altitudes.[8,9]

Specific Altitude-related Illnesses

Acute Mountain Sickness (AMS)

Acute Mountain Sickness syndrome affects 22 to 53% of travelers at altitudes between 1,850 and 4,240 m.[10] The diagnosis of AMS is essentially clinical based on the presence of headache plus one or more of the symptoms such as fatigue, anorexia, nausea, vomiting, giddiness and insomnia. The risk factors for AMS include the altitude reached and the rate of ascent. There are no specific physical examination findings or laboratory studies. AMS can be prevented by undertaking a slow ascent to high altitude areas. Acetazolamide and dexamethasone have been proven to be effective prophylactic agents.[11] Treatment requires cessation of ascent, symptomatic treatment with non-narcotic analgesics and acetazolamide in doses of 250 mg twice daily.

High Altitude Cerebral Edema (HACE)

HACE is a life-threatening condition characterized by the presence of ataxia, altered mental status (encephalopathy) or both in a patient with preceding symptoms of either AMS or HAPE. It is usually seen at altitudes above 4000 m. The main risk factor is rapid ascent to high elevations. Preventive measures are the same as that for AMS. Treatment requires immediate descent to lower elevations or recompression in portable hyperbaric chamber along with supplemental oxygen. Affected patients should also be treated with dexamethasone (loading dose of 8 mg followed by 4 mgq 6 hourly). If not recognized and treated immediately, HACE can even cause brain herniation and death.

High Altitude Pulmonary Edema (HAPE)

This is a noncardiogenic pulmonary edema that affects 0.2 to 15% of high altitude travelers.[12,13] It is usually seen at altitudes of above 3,000 m. HAPE occurs within two to five days of ascent and can either develop de novo or following symptoms of AMS or HACE. The main risk factors include the altitude, the rate of ascent, overexertion and cold-air exposure at high altitude. Individual susceptibility also plays a role, since susceptible individuals have been shown to have exaggerated pulmonary vascular responses to hypoxia and exercise at HAA.[5,6] The initial symptoms are vague and include decreased exercise performance and dry cough. With worsening disease, patients develop dyspnea on minimal activity and cough productive of pink frothy sputum. Physical examination reveals low-grade fever, resting tachycardia, tachypnea, cyanosis, and bilateral crackles. Prevention involves undertaking a slow ascent to high altitudes, avoiding overexertion and staged ascent to encourage acclimatization. Patients with a history of underlying respiratory diseases or pulmonary hypertension should be considered for prophylaxis with nifedipine 20 mg twice daily and/or inhaled salmeterol 125 μg twice daily.[14,15] This life-threatening disorder requires immediate descent to lower altitudes or recompression in a hyperbaric chamber with supplemental oxygen along with nifedipine 10 mg stat followed by nifedipine (sustained release preparation) 30 mg twice daily. Severe cases of HAPE can lead to severe hypoxemic respiratory failure and may require ventilatory support to correct severe hypoxemia and prevent fatal outcome.

Subacute Mountain Sickness (SAMS)

Subacute mountain sickness was described in Indian soldiers posted to elevations between 5800 and 6700 m for an average of 10 weeks.[16] The authors reported 21 cases of right heart failure that presented with dyspnea, cough and exercise-induced angina, had clinical evidence of pedal edema, polycythemia, cardiomegaly, pericardial effusion and ascites. It was postulated to occur due to an exaggerated hypoxic pulmonary vasoconstriction response leading to heart failure.[17] Treatment involved evacuation to lower altitudes, which usually leads to rapid resolution of the disorder.

Chronic Mountain Sickness (CMS)

This is a disorder, which usually develops in long-term residents with the stay of over one year at HAA. Monge et al[18] described a syndrome marked by the triad of polycythemia, hypoxemia and impaired mental function (headache, fatigue, impaired concentration and irritability). Clubbing and cyanosis may also be present. Treatment includes descent and stay at lower altitudes, periodic phlebotomy, diuretics and respiratory stimulants. Another form of CMS has pulmonary hypertension and right heart failure without polycythemia.[19] Treatment includes descent and stay at lower altitudes as the symptoms are known to recur on exposure to high altitudes.

Effects of High Altitude on Lung Diseases

Chronic Obstructive Pulmonary Disease (COPD)

There are numerous physiological derangements in patients with COPD, including impaired gas-exchange, reduced muscle strength and mild-to-moderate pulmonary hypertension. These patients are likely to have hypoxemia and worsened pulmonary hypertension at high altitude areas. Many studies have established that long-term residence at high altitudes is associated with increased mortality and a higher incidence of cor pulmonale in COPD patients.[20]

According to guidelines laid down by the American Thoracic Society, P_aO_2 should be maintained above 50 mm Hg during commercial flights.[21] The Aerospace Medical Association guidelines set this threshold at 55 mm Hg.[22] This target value is reasonable as P_aO_2 values in this range ensure arterial oxygen saturation above 85% and lie above the steep portion of the hemoglobin-oxygen dissociation curve. These cut off levels also serve as the guidelines for prescribing supplemental oxygen in-flight and during travel to high altitudes.[23] Most of these studies have included moderate-to-severe COPD patients without CO_2 retention, and therefore cannot be extrapolated to those with severe disease or with hypercapnia. The duration of exposure in these studies was shorter than what an individual would experience during a trip to high altitudes.

Another important issue in the COPD patient with severe bullous disease is whether the decrease in ambient pressure at high altitude predisposes to bulla expansion and pneumothorax? The available literature suggests that the physicians' concerns may be unwarranted. The bullae probably communicate with the airways to an extent greater than expected, allowing for pressure equalization to occur. The risks associated with scuba diving, where the pressure changes are greater are more than those with ascent to altitude, are much more.[1]

COPD patients with baseline FEV_1 less than 1.5 L should be assessed prior to high altitude travel to determine the need for supplemental oxygen. Prediction of the P_aO_2 at high altitude can be based on the regression equation provided by Dillard et al,[23] which is as follows:

$$P_aO_2 \text{ Altitude} = (0.5196 \times P_aO_2\text{SL}) + (11.856 \times FEV_1) - 1.76$$

Those with predicted P_aO_2 less than 50–55 mm Hg should travel to high altitude with supplemental oxygen. Patients should increase the flow rate of oxygen by 2 L/min when engaging in physical activity. Patients with preexisting pulmonary hypertension should be counseled against traveling to high altitude due to the high risk of developing HAPE or acute right heart failure. If the travel cannot be avoided, patient should travel with supplemental oxygen and should be started on nifedipine SR, 20 mg twice daily for duration of stay at altitude. Extreme caution should be taken with patients intending to travel to altitudes more than 3,048 m. Presently no data are available to guide recommendations above this elevation.[1]

Bronchial Asthma

There is reduced allergen load at high altitudes due to lower ambient temperature and humidity, therefore asthma exacerbations are inversely related to high altitude.[1] Hypoxia, hypocapnia and cold air can aggravate Bronchial Hyperresponsiveness (BHR) and worsen asthma control.[24] Protection of the nose and mouth from cold winds by using appropriate head gear helps to warm inspired air and must be used by all asthmatic subjects.[1]

The reduced air density at HAA should be beneficial for airflow limitation akin to effects of Heliox in asthma exacerbations, but these effects have not been studied systematically. The available data suggests that asthmatic subjects can travel to altitudes of up to 5000 m without any adverse effects for short-term trips. Patients with severe asthma should be advised against travel to HAA as they are likely to deteriorate and there is lack of medical facilities at most places. Patients must continue baseline medications and carry ample supply of rescue inhalers and oral prednisolone for any exacerbation. Peak expiratory flow must be measured and used for guiding self management plans.

Disorders with Pulmonary Hypertension

Several case reports suggest that those with pre-existing Pulmonary Arterial Hypertension (PAH) including those with altitude related PAH are at an increased risk for HAPE.[25] The severity of PAH in these reports have varied and it is not feasible to ascertain a threshold level for the risk. Patients with PAH may develop sudden rise in pulmonary artery pressure leading to acute right heart failure or progression to subacute mountain sickness on exposure to HAA.

Patients with PAH are advised to avoid travel to HAA. Those who cannot avoid the travel should be taught to recognize symptoms of HAPE and advised to use supplemental oxygen. Prophylaxis with nifedipine SR 20 mg BD for the entire duration of stay is also helpful. Phosphodiesterase inhibitor (sildenafil) and dexamethasone are other alternatives, which can be used for the prevention of HAPE.[26]

Pulmonary Thromboembolic Disorders

Those with past history of venous thromboembolism are at an increased risk for recurrence at HAA. Though there are no systematic studies, Anand et al[27] in a large retrospective study comprising of over 20,000 hospital admissions over 3 years period found 46 cases of vascular thrombosis (44 venous and 02 arterial) from HAA and 17 cases from low altitude areas. The calculated odds ratio of thromboembolic events at HAA was 30.5. The mean duration of stay of 10 months at HAA in patients who developed thromboembolic events cannot be extrapolated to shorter trips to high altitude areas. In the various case reports of thromboembolic events at high altitudes, a majority of subjects had the presence of pre-existing coagulopathy such as factor V Leiden mutation, protein C deficiency, hyperhomocysteinemia and use of oral contraceptive pills. From this it can be inferred that pre-existing prothrombotic state poses an increased risk for the development of thromboembolism at high altitudes.[1]

Patients with a history of venous thromboembolism who travel to high altitudes should continue their anticoagulation regimen and repeat coagulogram before and after their return from high altitudes. Women having underlying coagulopathy and using oral contraceptive pills should strongly consider discontinuing the use of oral contraceptives during their high-altitude exposure. Patients during their course of long flights or during other activities associated with a high degree of immobility, dehydration, or venous occlusion should be advised to maintain adequate hydration, regular movement and calf muscle exercises. An alternative strategy is to start low-dose aspirin during their stay at HAA.[1]

Interstitial Lung Disease

Of all the respiratory diseases, least data is available regarding the effects of high altitude on patients with ILD. There are reports of worsening dyspnea, resting hypoxemia and exercise-induced desaturation in patients with ILD.[28] In addition, most ILD patients have PAH and are at increased risk of developing HAPE.

Patients with ILD need assessment for need for supplemental oxygen based on the regression equation proposed by Christensen et al: [29]

$$P_aO_2 \text{ Altitude} = 50.74 + (0.396 \times P_aO_2SL) + (0.0336 \times TLC)$$

The patients with P_aO_2 levels between 50 and 55 mm Hg should receive supplemental oxygen during their travel to high altitudes. Patients with ILD and PAH are required to start nifedipine prophylaxis against HAPE. [1]

Pneumothorax

Those with pneumothorax and those following thoracic surgery are advised to wait for two weeks after resolution to undertake travel to HAA. Travel to HAA of patients with persistent pneumothorax or bronchopleural fistula with an *in situ* chest tube or Heimlich valve is considered safe. It is recommended to screen patients at high risk for secondary spontaneous pneumothorax for the presence of occult pneumothorax with CT scan prior to high altitude travel.[1]

Ventilatory Disorders

There is some data to suggest that obese individuals are at a risk of developing altitude induced pulmonary hypertension. Patients with obesity hypoventilation syndrome and obstructive sleep apnea are at increased risk for developing AMS, heart failure and HAPE. These patients should be advised to avoid travel to HAA. If the travel cannot be avoided, supplemental oxygen and acetazolamide in the dose of 125 mg or 250 mg BD are required. Patients with pulmonary hypertension should also start nifedipine SR 20 mg BD for prophylaxis against HAPE. Those patients on domiciliary CPAP therapy are advised to travel to high altitudes with CPAP unit and make necessary adjustments in set pressure for machines lacking pressure compensation.[1]

CONCLUSION

The pathophysiology of high altitude-related illnesses has been well documented in healthy individuals, but little is known about the risks of high altitude travel in patients with pre-existing lung diseases. The deranged physiological functions in patient with lung disease are aggravated at high altitude, lead to worsening of hypoxemia and of respiratory failure and predispose to the occurrence of HAPE. The presence of lung disease does not always preclude travel to high altitude. The travel may be safely carried out provided a thorough evaluation is done and adequate prophylaxis has been started to prevent ARI or worsening of the underlying lung disease.

Aviation and Space Travel

Ajay Handa

AIR TRAVEL

Air travel has become the preferred mode of travel in most instances due to convenience and saving of time. Worldwide, over one billion passengers travel by air each year. The vast majority of people who travel by air are healthy individuals, but approximately 5 to 10% of passengers have underlying diseases, such as the respiratory ailments, including Chronic Obstructive Pulmonary Disease (COPD).[1] The prevalence of respiratory diseases is increasing worldwide and most such patients do prefer to travel by air to minimize discomfort. Many patients consult their physicians prior to planning air travel for fitness and prescription of supplemental oxygen during flight. Patients who have suffered from an acute medical ailment in the period preceding the air travel, or those with previous cardiopulmonary disease are particularly concerned. The knowledge of aviation physiology and medicine is important for pulmonary physicians to handle patients with chronic respiratory diseases.[2]

Respiratory Problems During Air Travel

The fall in partial pressure of oxygen with high altitude can cause hypobaric hypoxia during air travel. Commercial aircrafts fly at the height of 10,000–13,000 meters Above Sea Level (ASL), pressurization in the cabin is maintained to keep the level at about 2438 meters ASL. For technical reasons, the cabin altitude cannot be maintained at lower than 2438 meters. Breathing at this altitude (15% oxygen) causes the PaO_2 to fall to 53–64 mm Hg (SpO_2 85 to 91%). This mild hypoxemia does not produce any symptom, is well tolerated in healthy subjects, but it may cause significant hypoxemia and precipitate respiratory failure in patients with chronic lung disease.[3] Such patients need thorough preflight evaluation and recommendation to use supplemental in-flight oxygen.

Another physical effect of ascent to high altitudes is the expansion of gases due to decrease in ambient pressure (Boyle's law). The expansion of gas trapped in close cavities, such as the middle ear and the intestine can cause discomfort. The gas within a lung bulla will expand by 30% at 2450 m ASL, cause rupture and recurrence of complication of pneumothorax, pneumomediastinum and air embolism.[4] Patients of COPD with emphysematous bullae at increased risk for pneumothorax and respiratory failure during air travel are advised to avoid air travel. Due to the risk of the development of respiratory distress, untreated pneumothorax is the only absolute contraindication for travel by air.[1]

The analysis of in-flight emergencies from various studies has shown that respiratory problems account for 10% of all medical emergencies. This is the third leading cause of in-flight medical emergencies after cardiac and neurologic emergencies. Exacerbations of asthma and of COPD are the most common respiratory problems, which are encountered during air travel.[1]

Preflight Assessment

The aim of preflight assessment is to identify those individuals who are likely to develop significant hypoxemia onboard the flight. Patients on Long-term

Oxygen Therapy (LTOT) and those with cardiorespiratory illnesses constitute important categories. Patients with severe COPD, bronchial asthma, restrictive lung diseases, past venous thromboembolism, recent pneumothorax and pulmonary tuberculosis are at high risk of deterioration during air travel and must be subjected to preflight screening.[5] Patients with recent cerebrovascular accidents and congestive heart failure may also worsen on air travel and need to be assessed accordingly. In cardiac patients travel on commercial airlines is fairly safe after two weeks of myocardial infarction without the requirement of supplemental oxygen.

Preflight assessment should include detailed medial screening and counseling. The three methods usually adopted for preflight evaluation for oxygen supplementation include 50 meters walk test, use of prediction equations and the hypoxic challenge test.[1]

Airline medical authorities traditionally use the 50-meter walk test for screening passengers. Those who are able to walk 50 meters are considered “fit to fly”. The test provides a crude assessment of cardiorespiratory status and requires supervision. Failure to complete the distance or the development of moderate-to-severe respiratory distress should alert the physician to referral for assessment for in-flight oxygen by respiratory physician.

Nomograms and prediction equations for PaO_2 at altitude using blood gas parameters and spirometry at ground level have been developed through studies in COPD patients exposed to hypoxia (Table 104.1).[6] In clinical practice, such equations are most frequently applied to predict fitness and requirement of on board oxygen. Predicted PaO_2 value of less than 50 mm Hg constitute an indication for supplemental in-flight oxygen.[1]

There are no guidelines as to which of the above equation is to be used. Some authors use regression equation for calculating predicted PaO_2 at a particular altitude. If the calculated value is in the range of 50±3 mm Hg, hypoxic challenge test is advised for definitive recommendations.

The hypoxic challenge test remains the gold standard for preflight assessment regarding oxygen supplementation.[1,7] The subject is exposed to 15% oxygen in nitrogen using nonrebreathing facemask or body plethysmograph. Continuous monitoring with pulse oximetry and electrocardiography is done to prevent severe desaturation and to detect cardiac arrhythmias. Arterial blood gas analysis is done before and after the hypoxic exposure. The mean predicted altitude PaO_2 derived from regression equations compares well with actual PaO_2 obtained during the hypoxic challenge tests. Considering the limited availability of facilities for hypoxic challenge testing for a large numbers of patients with respiratory diseases and COPD who travel by air, the British Thoracic Society Guidelines[1] recommend that oxygen saturation measured by pulse oximetry can be used to initially screen groups of passengers. Those with SpO_2 of less than 92% are advised in-flight oxygen and those with SpO_2 between 92 to 95% are prescribed hypoxic challenge test (Table 104. 2).

Those passengers who have additional risk factors, such as hypercapnia, FEV_1 less than 50%, presence of predicted diseases such as lung cancer, restrictive lung diseases, comorbid cardiovascular or neurological diseases and those who are within six weeks of discharge from hospital for acute exacerbation, shall require hypoxic challenge testing.

The patients subjected to hypoxia challenge are categorized based on the measured PaO_2 after 15 min at FIO_2 15% and advised accordingly based on PaO_2 (Table 104.3).

TABLE 104.1: Equations for calculating predicted PaO_2 at 2450 m

1. PaO_2 altitude = 0.84 + 0.68 (PaO_2 ground)
2. PaO_2 altitude = 0.295 (PaO_2 Sea level) + 0.086 (FEV_1 % predicted) + 23.211
3. PaO_2 altitude = 0.245 (PaO_2 Sea level)+ 0.171 (FEV_1/FVC % predicted) + 21.028

TABLE 104. 2: BTS recommendations for initial screening

Pulse oximetry	*Recommendation*
SpO_2 > 95%	Oxygen not required
SpO_2 92% to 95% without risk factors	Oxygen not required
SpO_2 92%–95% with risk factors	Hypoxic challenge test
SpO_2< 92%	In-flight oxygen

TABLE 104.3: BTS recommendations after hypoxic challenge test

Blood gas report	*Recommendation*
PaO_2 >55 mm Hg	Oxygen not required
PaO_2 50–55 mm Hg	Borderline, advised 50 m walk test
PaO_2 <50 mm Hg	In-flight oxygen (2 l/min)

Prescribing In-flight Oxygen

Any patient with PaO_2 of less than 70 mm Hg ASL at rest will require supplemental oxygen during air travel.[8] Most commercial airlines provide in-flight oxygen on advance request and physician's prescription. The expenses are required to be borne by the travelers.

The oxygen is usually provided from cylinders during travel. The rate of flow and duration should be specified to assess the adequacy of oxygen during the journey. The flow rate of oxygen of 2 l/min is suitable for most passengers. Those on LTOT are advised to increase the flow rate by 2 l/min above the usual flow rate.[9]

Most airlines provide oxygen through simple face masks, passengers are advised to carry their nasal prongs to prevent rebreathing. The oxygen and cabin air inside the aircraft are devoid of moisture, which may cause drying of tracheobronchial mucosa and precipitation of bronchospasm. The airlines should be informed for the need of humidified oxygen for patients with asthma and COPD. In addition, such patients must be advised to carry their medications in their hand baggage for use in emergency situations.[10]

Airlines do not provide oxygen during waiting period and stopovers. Some airports restrict oxygen use because of the risk of explosion. Oxygen-dependant patients must make additional arrangements for use during the waiting periods at the airports. Patients cannot use their own cylinders or concentrators, but may be able to take these items with them as baggage for use at their destination. It is also important for these patients to carry their medical documents and extra-drug supplies during travel (Table 104.4).

Conclusions

For most passengers, air travel is safe and comfortable. Patients with cardiorespiratory diseases are at risk of significant hypoxemia during air travel. Most of these individuals complete the journey uneventfully with supplemental oxygen. All the present recommendations are based on the results of effects of simulated hypoxia on patients with lung diseases. More investigations are required on the effects of air travel on passengers with lung diseases.

TABLE 104.4: Guidelines for oxygen-dependent patients prior to air travel[11]

- Obtain medical certificate of fitness to fly
- Carry prescription of in-flight oxygen requirement
- Inform the airlines while booking tickets and 48-72 hours before date of journey
- Inform airlines need for oxygen before boarding and during stopovers
- Preferably take nonstop flight to destination
- Carry extra tubing and personal nasal cannula
- Carry extra copies of prescriptions and medical certificate
- Carry emergency supply of medications in hand baggage

SPACE TRAVEL

The effects of gravity and of its absence on respiratory physiology have intrigued scientists since time immemorial. The condition of zero gravity or weightlessness (microgravity) for assessing its effects on human body can be achieved by two methods. These are parabolic flight in aircrafts and space flight. The parabolic flights in commercial jet aircrafts are associated with the small periods of microgravity with thr periods of hypergravity (increased gravitational forces) during these maneuvers. Parabolic flight is more easily available and less expensive compared to space flight. It has the disadvantage of creating motion sickness on passengers during this "roller coaster" flight. The US, Russian and the European Union countries have regular parabolic flights for their research work.

Flights in spacecrafts are infrequent and extremely expensive. Space flights have sustained periods of microgravity from one week to up to a year. Most research work on space medicine has been done on board Russian space station, Mir and International Space Station (ISS) led by the USA. These space stations offer convenient environments for studying the effects of space on human physiology. The number of subjects is often limited to four, the crew serve as subjects and operators or both. Evaluation includes preflight and postflight testing of various parameters and their comparisons with data under microgravity.[12]

Microgravity and Weightlessness

There are some ground-based experiments, which mimic weightlessness such as the six degrees Head-Down Tilt (HDT) and Thermoneutral Water Immersion (TWI). These have been useful to study the cardiovascular and musculoskeletal responses. The significant effect of gravity on the lungs and pulmonary vasculature cannot be removed by these experiments. Furthermore, HDT and TWI caused larger reductions in resting lung volumes than microgravity, which cannot be ignored.[13]

To understand the effect of microgravity and weightlessness in space on the respiratory system, we can take a cue from the common knowledge that even though there are no structural differences between the upper and lower parts of the human lungs, gravitational forces lead to marked functional differences between these areas. The alveoli at the top of the lung are more expanded compared to those at the bottom of the lung, because of the weight of the lungs on the lower parts. On the other hand, the alveolar ventilation is higher at the bottom of the lungs as compared to that at the apex. Gravity also influences the intrapleural pressure, parenchymal stress and pulmonary blood flow, which may result in regional differences in lung function.[14,15] There is a great disparity in the pulmonary blood flow between the top and the bottom of the lung, with greater flows at the bases in comparison to that at the apices. This is due to the effect of hydrostatic forces on the low-pressure pulmonary circulation. As a result of the profound effects of gravity on alveolar ventilation and pulmonary perfusion, ventilation perfusion ratio $\dot{V}/\dot{Q}$ is higher at the apices than at the lung bases and there are regional differences in gas exchange in the lungs.[16]

The influence of gravity on the lung on earth and by increasing the gravitational effect has been studied. Most of the changes in lung function are attributable to gravity. The conclusions of these studies cannot be extrapolated to zero gravity conditions. A large number of studies on the respiratory functions in the absence of gravity have been performed in the last decade and a half. The results of some of these studies are summarized here in the succeeding paragraphs (Table 104.5).

Effects on Lung Volume and Spirometry

The first study on lung volumes during space travel, done in 1970s showed that Vital Capacity (VC) was reduced by 5 to 10%.[17] The subsequent studies have shown that VC reduction by 5 to 6% for the first-two days, which normalizes by the day four, onwards. This was explained by the early in-flight increase in intrathoracic blood volume, which subsequently reduces to normal, as the plasma volume reduces during the sustained space flight.[18] As the effect of gravity was removed, the Functional Residual Capacity (FRC) reduced by 5 to 10% due to cranial shift of diaphragm and outward movement of the ribcage.[19] Residual Volume (RV) remains unchanged with microgravity.[20]

Peak Expiratory Flow (PEF) remained unaffected in most studies.[21] During the initial space flight, there was a reduction in the PEF due to the lack of a firm platform to push against during the forced expiration, there was subsequent recovery attributable to better performance after adaptation to microgravity. There was no change in Forced Expiratory Flow (FEF) in the effort independent portion at lower volumes (i.e. FEF 25 to 75%), which suggested that behavior of the central and peripheral airways as well as the respiratory muscles was unaffected in space.[21]

TABLE 104.5: Summary results of studies on effects during space travel on pulmonary function

Effects	*First findings*	*Afterwards*
1. Lung volumes and flows		
• VC	Reduced	Normalized
• FRC	Reduced	Normalized
• RC	Unchanged	
• PEF	Unchanged	
• $FEV_{25\text{-}75\%}$	Unchanged	
2. Pulmonary diffusion		
• DLCO	Increased	Increased
3. Gas exchange		
• Tidal volume	Reduced	
• Respiratory rate	Increased	
• Minute ventilation	Marginal decrease	
• Physiological dead space	Reduced	
• Oxygen consumption	Unchanged	
• CO_2 production	Unchanged	
4. Cardiac output	Increased	–
• Heart rate	Increased	–
• Stroke volume	Unchanged	–
5. Response to exercise		
• Cardiac	Reduced	–
• Ventilatory	Unchanged	–
6. Ventilatory control		
• Hypoxic drive	Reduced	–
• CO_2 drive	Unchanged	–
7. Sleep		
• Sleep efficiency	Poor	Poor
• Sleep apnea syndrome	Reduction in events and snoring	

Effects on Diffusion Capacity and Pulmonary Perfusion

There was substantial increase in diffusion capacity by 28% over the baseline and it remained elevated over the course of nine-day flight, due to an increase in pulmonary capillary blood volume and membrane diffusing capacity.[22] These phenomena were attributed to transition of the lung from its zone 1, 2, 3 $\dot{V}/\dot{Q}$ configurations on ground level to zone two or zone three in entirety in space causing a more uniform capillary filling.[22]

Effects on Gas Exchange and Ventilation Perfusion Relationship

The tidal volume was reduced and breathing frequency increased, thus the minute ventilation was reduced only marginally.[23] Moreover, the physiological dead space reduced, thus the effective alveolar ventilation remained the same. In spite of these ventilatory changes, studies have shown that oxygen consumption and carbon dioxide production remained unchanged in space.[23] The peak oxygen consumption however reduced by 22% on return to ground and gradually recovered over the next six to nine days to the preflight levels, postulated to be due to circulatory blood volume changes.

Effect on Cardiac Output and Exercise

Cardiac output increased after two weeks in space as a result of increased heart rate with constant stroke volume.[24] The ventilatory response to exercise remained unchanged in microgravity, but the cardiac response to exercise was less in short duration space flights when compared to ground level changes. No data is available for long duration space flights.[25]

Ventilatory Control and Sleep in Space

There was substantial reduction in the ventilatory response to hypoxia with halving of hypoxic drive, whereas the response to carbon dioxide remained unchanged. This change in the hypoxic response was possibly due to an increase in blood pressure at the level of the carotid bodies due to zero gravity. The systemic blood pressure remained unchanged, but the blood pressure at the carotid bodies was higher due to the abolition of hydrostatic pressure difference normally present on ground.[26]

There was poor sleep efficiency during space flights, these were related to poor ventilatory control and altered circadian rhythm.[27] The subjects with obstructive sleep apnea syndrome had improvement in sleep quality with reduction in events and snoring. The cause of sleep deficiency in space is not related to respiratory system changes.[27]

CONCLUSION

It can therefore be concluded from the comprehensive data on changes in respiratory physiology in space that the effects are generally benign and unlikely to limit the activities of astronauts in space.

Diving Medicine

Angeline Lazarus, Richard Mahon

Whether due to occupational requirements or recreational choices, exposures to extreme environments impose some significant health risks. One unique environmental exposure is water diving to various depths for recreational, commercial and military purposes. While free-water diving has been practiced for centuries, it was the introduction of the Self-contained Underwater Breathing Apparatus (SCUBA) by Cousteau and Gaston in 1942 that triggered a dramatic increase in diving and its popularity as a recreational sport. Currently more than 10 million individuals participate in diving for recreation, competition or occupation. Diving requires physical and emotional stamina that may be limited by medical conditions that would increase the risks of this environmental exposure. Pulmonologists and other medical specialists are called upon to assess an individual's health status either prior to dive training, or after a dive and decompression exposure to evaluate and treat associated complications. This chapter on diving medicine will generally cover the types of diving, physiological aspects, medical conditions resulting from diving, and the management of diving related injuries/ illnesses. With advances in technology and knowledge of diving, human beings are able to dive to greater depths relatively safely.

HISTORICAL BACKGROUND

One of the first instances of man overcoming the limitations of simple breath hold swimming was recorded in 332 BC, when Alexander the Great descended to the seabed in a glass barrel during the siege of Tyre. Since then, diving equipment has evolved from simple diving bells that allow a diver to breathe trapped air with to modern day sophisticated rebreathing apparatus. The development of caissons for building bridges and technology for surface-supplied breathing mixtures significantly increased the time an individual could remain under pressure. With such advances came a greater understanding of the unique and complicated aspects of diving physiology and its inherent risks. In the beginning we knew little about the physiological changes that occur during diving and decompression. In the 17th and early 18th century, technological improvements included replenishing the air in diving bells to increase time at depth. In the 19th century, compressed air delivered from the surface using helmets was commonly used and the 20th century brought independent breathing systems that freed the diver from the surface and spurred on today's popularity. Also in the 19th and 20th centuries, an understanding of decompression sickness began to emerge. Descriptions of decompression sickness were first detailed the written observations of Haley (1716) and Triger (1845) and since than numerous descriptions of this syndrome are available.[1]

DIVING PHYSICS AND PHYSIOLOGY

Diving is an underwater strenuous activity where environmental conditions have an impact on the organs and functions of the body. At normal surface exposure, humans are exposed to an ambient pressure of 750 mm Hg [100 kPa = 1 bar = 1 standard atmosphere (atm)]. Underwater, pressure increases with depth at a rate of 1 atm increase for every 10 meters descent. Recreational divers go to depths as deep as 40 meters, while commercial and military divers (occupational divers) may explore depths greater than 500 meters in the open ocean. In a hyperbaric chamber, descent to a pressure equivalent to a depth of 700 meters has been recorded.[2]

To be able to move the bellows of the lung, internal pressure must be equilibrated with the ambient pressure. Achieving this balance through the use of compressed gas exposes the diver to two basic laws of gas physics as described by Boyle and Henry. Boyle's law states that the volume of a gas is inversely proportional to the pressure applied to it when temperature is constant. That is to say, for every 10 meters of depth, pressure increases by 1 atm and air volume decreases by 50%. A corollary of this is the reversal that occurs during ascent to the surface. Organs and cavities that hold gas are therefore more greatly affected by compression and decompression. According to the gas laws and pressure-volume relationships, gas compresses within body organs, such as lungs, sinuses, middle ear, and intestine during descent, and similarly that same gas expands during ascent. Hence, this single phenomena explains something as relatively harmless as an "ear squeeze", as well as catastrophic pulmonary injury that can result in an air-gas embolism or pneumothorax.[3-5]

According to Henry's law, at constant temperature, the amount of gas dissolved in a liquid is directly proportional to the partial pressure of that gas. The increased pressure of a diver's breathing gas causes that gas to dissolve in body fluids and tissue in proportion to the pressure increase. While oxygen is metabolized, physiologically inert gases, such as nitrogen remain in solution. As pressure decreases during ascent, the dissolved gas can come out of solution, forming bubbles, and resulting in decompression sickness. A gradual decrease in pressure can allow the inert gas to slowly come out of solution and be exhaled, thus minimizing decompression sickness.[3-9] So called "diving tables" were painstakingly calculated to estimate the amount of gas dissolved in tissue beds (based on time and depth) during the compression phase of diving to determine the ascent rate for the safe elimination of excess gas during decompression. These dive tables are reliably used in military and recreational diving.[8]

In addition to the laws of gas physics, immersion in water itself has multiple effects. Though outside the scope of this review, water immersion can shift intravascular blood to the thorax and increase peripheral vasoconstriction. The increased energy transfer of water when compared to air can not be overstated and also explains why water immersion increases the risk of thermoregulatory concerns.[9,10]

TYPES OF DIVING

Apnea diving, otherwise known as breath-hold diving, is the oldest type of diving. Female apnea divers in Japan and Korea can boast a long history of collecting pearls from shellfish and harvesting seafood. In the recent years, apnea diving has become a competitive sport, the goal to achieve the maximum dive depth and longest dive duration. Breath-hold duration depends on the diver's ability to withstand hypercapnia and hypoxia. Breath-hold divers train to minimize metabolic rate, increase lung capacity and develop psychological tolerance to overcome the sensation of asphyxia. Though apnea divers generally stay underwater for less than five minutes, world record breath-hold times in excess of 11 minutes and depths up to 200 meters illustrate remarkable limits of tolerance. One overt risk in breath-hold diving is that increases in the partial pressure of oxygen can mask the decrease in oxygen content, until one nears the surface. The marked decrease in oxygen partial pressure certainly translates into a high risk of black-outs and drowning.[11-15] One method to increase Total Lung Capacity (TLC) and the TLC/Residual Volume (RV) ratio practiced by some breath-hold divers is known as buccal pumping or "lung packing". Following a full inhalation to TLC, further air intake is achieved by keeping the glottis open and forcing more air into lungs; this may increase capacity to an additional 39%.[16]

Commercial Diving

Commercial divers are exposed to a broad-spectrum of diving variables, such as depth, temperatures, salinity and contamination. These exposures coupled with the responsibility of their livelihood, puts them at increased risk for physiologic and psychologic stresses. Commercial divers are skilled in diving, as well as their underwater work requirements. They must master the safe operation of a wide array of industrial equipment, such as welding machinery. In addition, they must achieve and maintain a higher standard of physical and mental strength, endurance, dexterity, flexibility, adaptability and situational awareness. It is well known that physiologic stresses adversely impact performance and safety. In the case of commercial divers these include thermal stress, environmental stress, workload stress, oxygen stress, inert gas stress and decompression stress. Some stresses can be mitigated, for example with diving helmets and/or protective suits. Dive helmets of course provide head protection, but also reduce the breathing effort and minimize respiratory dead space.

Fig. 105.1: Commercial diving

Conventional helmets use an oronasal mask to reduce the reinhalation of carbon dioxide. Protective suits prevent direct skin contact with the surrounding water, providing both thermal and hazardous waste protection[17-19] (Fig. 105.1).

Two major types of commercial applications are surface-based diving and saturation diving. In surface-based diving, the diver is situated at work depth for a fixed length of time and ascends following the standard decompression tables. This dictates, and thereby limits their productivity. Saturation diving is so named because the diver's tissues are fully saturated with gas. Once saturated, a diver can remain under that pressure without incurring further obligations for decompression. Generally in saturation diving, a team of divers descends to working depth in a decompression chamber where they remain under pressure for an extended time working in shifts and spending their "leisure" time remaining at that pressure. When the job is completed they undergo one single decompression within the same chamber.[17,18]

Recreational Diving

Fig. 105.2: Scuba diving

Diving as a recreational sport has gained popularity over the last few decades with the development of SCUBA (Fig. 105.2). Many organizations have emerged to provide safety training for SCUBA diving. There are three major types of recreational diving. The most common is the "open-circuit SCUBA" using compressed air; it is technically simple, easily to learn and inexpensive. In open-circuit diving, air is inhaled through regulators from a high pressure tank and exhaled into the environment. In general, open-circuit diving is for depths of less than 40 msw time restrained by the limited supply of gas in the tank. The second type of recreational diving is "technical SCUBA" where divers use more complex equipment and breathing gas mixtures and dive to greater depths than open-circuit SCUBA. Technical diving requires more sophisticated equipment and extensive training. The third type of recreational diving is the "semi-closed" and "closed SCUBA" where exhaled gas is recycled through a chemical chamber that removes carbon dioxide. While this feature enables longer dive durations, the consequences of any malfunction that would accumulate carbon dioxide could lead to significant adverse effects.[20-23]

Diving certification agencies, such as Diver Alert Network (DAN) and Diving Emergency Services (DES) are established to support recreational diving with safety a primary concern. Many countries have instituted safety and training requirements for recreational diving.

DIVING-RELATED INJURIES/ILLNESSES

As the depth and duration of diving have increased over the years, so too has the number of divers participating for sport and recreation. Fortunately, this has motivated research into understanding the pathophysiology and treatment of diving-related injuries. In general, these are classified into four types of adverse events:

1. Decompression Sickness (DCS)
2. Barotrauma affecting cranial sinuses, ear, and pulmonary (and resulting in arterial gas embolism)
3. Toxicity of increased partial pressure of gases, nitrogen narcosis
4. Pulmonary edema

Other complications associated with scuba diving that are not included in this discussion are hypothermia, trauma, drowning and marine envenomations.[24-29]

DECOMPRESSION SICKNESS

Pathophysiology of Decompression Sickness

Bubble formation from dissolved inert gas in blood and tissues is considered central to the pathophysiology of decompression sickness. As ambient pressure decreases, the ability of tissue to dissolve inert gas is exceeded, a state known as super-saturation. If this excess gas is not exhaled, this inherently unstable state may lead to bubble formation in the vascular system (most commonly) or within tissue beds. The vast majority of bubbles in the vascular system are detected in the venous/right heart and pulmonary artery. In most divers, venous bubbles can be detected within the minutes of surfacing; they are generally trapped in the lungs from where they are safely eliminated. However, bubbles may bypass this filter mechanism in the presence of right-to-left shunts, such as seen in Patent Foramen Ovale (PFO). Additionally, large bubble loads may overwhelm the filtering capacity of the lung capillary bed and become "arterialized." These bubbles damage the endothelial cells and luminal surfactant layer, especially in the lungs and the cerebral vessels. Bubbles can interact with blood components leading to platelet aggregation, affect leukocytes, increase cytokines release, impact the coagulation pathway, and activate complements. Bubble damage to the pulmonary vasculature can result in the release of leukotrienes, blood-lung barrier injury, elevated pulmonary artery pressure, decreased cardiac output, pulmonary edema and hypoxemia. In severe cases, these changes may lead to cardiac failure, respiratory arrest and death (known as the "chokes").[30-32]

Bubble detection by Doppler ultrasonic techniques has become a valuable research tool. Yet, the fact that bubbles can be demonstrated in divers after surfacing contradicts the low incidence of DCS. Clearly, much remains to be learned.[31]

Clinical Presentation of DCS

Decompression disorders were originally referred to as Caisson's disease, compressed air illness or tunnel disease. Other terms, such as diver's palsy, "chokes", and "staggers" pointed toward the multiple system involvement. The commonly recognized term "bends" described limb pain, calling attention to Caisson workers walking "bent" over from pain. Matthews used the term decompression sickness in 1939. In the mid-to-late 20th century, the further classification of DCS was established. The current classification was first described by Elliott and Kindwall.[31]

DCS is a systemic disease with generally focal manifestations. Various strategies have attempted to classify DCS syndromes. In reality, there is not often a clear distinction between mild and severe DCS and there is considerable clinical overlap with Arterial Gas Embolism (AGE). In general, DCS presentation is somewhat delayed compared to AGE. A few common accepted classifications are outlined below.

One method to classify DCS severity uses the terms Type I and Type II. Type I DCS is milder with divers reporting joint pains, pruritis and skin rash. Type II DCS is a more severe manifestation that may result in cardiopulmonary compromise, neurologic injury and death. Neurologic injury from DCS likely results from gas bubbles obstructing regional blood flow with clinical symptoms, such as blurred vision, paresthesias, paraparesis, convulsions and death. Golding (1960) reviewed 685 cases of DCS and classified them as Type I for simple clinical manifestations and Type II for serious manifestations. In his review, the majority of DCS was considered Type I. With advanced diagnostics and diving technology, the differentiation between the two types is not always clear and they may coexist.[33]

Multiple databases are maintained in the commercial, military and recreational diving communities. The collection of data for recreational divers remains a challenge as it is likely that not all DCS is reported or recognized. One large recreational database is maintained by DAN. In addition to extensive educational resources, DAN publishes an annual compilation of diving-related injuries. More recent reports of manifestation frequency differ from earlier reports, especially in sport divers. DCS is a multisystem disease with diverse manifestations that differ with the type of diving. For example, while military divers report limb pain as most common, sport divers most frequently report neurologic symptoms, nearly 50% being altered sensation.[31]

Cutaneous Manifestations

Diving may produce skin itching, thought to be secondary to bubbles within the hair follicle. While this may be uncomfortable, it is not considered to be DCS. Cutaneous marmorata, a skin manifestation is a symptom of DCS characterized by purplish discoloration, which results from transcutaneous bubble migration causing vasospasm, release of inflammatory mediators and complement. Though considered mild, cutaneous manifestations may predict the development of more severe DCS. Also considered are the rarely observed lymphatic forms of DCS. Localized swelling from lymphedema is thought to result from a bubble obstruction of lymphatics; this condition resolves without further therapy.[5,22,34-36]

Constitutional Symptoms

Constitutional symptoms, such as fatigue, malaise, anorexia, poorly characterized muscle pains and headache are commonly reported. It is unclear if these are the result of decompression, thermal regulation, dehydration or environmental changes. This aspect of diving has not been thoroughly studied, but the proinflammatory effects of bubbles may also have an impact. In such cases, complaints must be clinically evaluated and a detailed neurologic exam performed to exclude focality.[5,22, 34-36]

Neurologic Manifestations

The data from DAN in the 1990s show the most common manifestations as neurologic, ranging from 40 to 77%. The predominant neurologic symptoms are paresthesias (tingling/numbness). These symptoms generally occur shortly after ascent and the loss of consciousness was frequently noted. Another CNS manifestation soon after is numbness and weakness in the legs that progresses overtime. There may also be pain, bladder dysfunction and rarely bowel dysfunction. Most commonly involved are the thoracolumbar and the cervical cord. The majority of cases report sensory changes without objective changes. Theories to explain the mechanism of spinal cord involvement include arterial bubble embolism, agglutination of blood elements, venous infarction hypothesis, activation of complement hypothesis, and autochthonous bubble hypothesis.[5,22,34-37]

Musculoskeletal Manifestations

Pain in the extremities was reported as the second most significant symptom following neurological symptoms. In the 1998 DAN data, pain in the arm was 3–5 times more common than pain in the legs. However, divers that decompress from saturation or near saturation tend to manifest leg pain more frequently. The character of the pain is often a deep ache close to a joint, but without joint swelling or inflammation.[22,25,34]

While no single mechanism for joint symptoms is proposed, autochthonous bubble formation is most likely. Gas formation in a joint and bone marrow cavity results in pain. Another hypothesis suggests the possibility of referred pain from an injury to central and peripheral nerves, but animal studies did not support this.[38]

Risk Factors for Bubble Formation and DCS

Even though many factors that might either predispose a diver to bubble formation or predispose tissues to bubble injury, true correlations are lacking. It is difficult to resolve the fact that the vast majority of dives are associated with intravascular bubble activity, yet the incidence of DCS is only 1:10,000 dives. There is significant intersubject variability in the incidence of bubble formation despite similar diving depths and duration. Some diver-specific risk factors that have been suggested include the percentage of body fat, as nitrogen is more soluble in lipids than aqueous tissues, advancing age with possible less physiological reserve, history of previous DCS, dehydration prior to the dive, female gender, poor physical fitness, and PFO. Some nondiver-related risk factors for DCS are the duration and depth of the dive, the ascent rate, repetitive dives, exercise under pressure, exposure to cold, and exercise after decompression.[32,33]

One factor that may increase DCS risk is the right-to-left shunt. All intracardiac right-to-left shunts increase the risk of paradoxical air emboli. Venous bubbles may cross Patent Foramen Ovale (PFO) (or other right-to-left shunts). Normally the direction of flow across the PFO is from left-to-right. When there is pulmonary hypertension with DCS, or large amount of bubbles, a reversal of flow can occur, putting bubbles in the arterial circulation. This reversal can cause significant disease in humans.[39-41] Moon and associates reported 61% of those with PFO who developed DCS had neurologic manifestations.[29] Wilmhurst and associates showed 52% of 100 divers with neurologic DCS had medium-to-large shunts compared to 12.2% of 123 divers without DCS. Even in asymptomatic humans, 20 to 34% are reported to have PFO. Hagen and associates reported 31% of divers who never had DCS had PFO.[42] Though, it appears that there is an association between PFO and DCS risk, the significance is unclear and controversial.[42-44] The current practice is not to screen every diver for PFO with a bubble-contrast echocardiogram; however screening for PFO after a DCS appears reasonable and may better inform the diver and the practitioner.[42]

Since cabin pressure in commercial planes is not maintained at one ATM, it stands to reason that flying after diving would have significant interactions. Air travel within 12 hours following a single dive or within 48 hours following multiple dives may increase a diver's DCS risk in flight. Divers should avoid flying during this high-risk period. Furthermore, when seeking medical attention for a postdive event, divers must be thorough in reporting to a physician who may not make the historical connection and recognize DCS manifestations.[45]

Certain coexisting medical conditions increase the risk for DCS. While pregnancy is not an absolute contraindication for diving, pregnant women should be advised against diving as fetus may suffer from DCS.[45-48]

Patients with intra-atrial shunts, ventricular arrhythmias, or congenital QT syndromes are at high risk for DCS. The British Thoracic Society has established guidelines for the respiratory evaluation of divers that provide key points essential for clinical assessment before diving[5] (Tables 105.1 to 105.3).

TABLE 105.1: The diving environment

- Diving is an arduous underwater activity in which environmental conditions affect bodily structure and function.
- For every 10 meters descent in sea water, ambient pressure increases by 100 kPa, equivalent to 1 atmosphere (1 bar). The volume of a given mass of gas changes inversely in proportion to pressure. The gas in bodily cavities, such as the lungs, sinuses, middle ear and intestine is therefore subject to compression during descent and expansion during ascent. This may lead to tissue damage.
- Partial pressure of gases increases in direct proportion to the increase in ambient pressure. Greater quantities of inert gas, mainly nitrogen, therefore dissolve in tissues at depth and come out of solution on ascent.
- The density of inhaled gas increases with pressure, restricting breathing.
- Immersion displaces blood from the periphery into the thorax, reducing lung volume.
- Work of breathing increases due to a combination of increased gas density, increased hydrostatic pressure, and altered respiratory mechanics.
- Underwater breathing apparatus adds dead space and increases resistance to breathing.
- During diving, carbon dioxide retention may result from the above listed effects on the body.

TABLE 105.2: Summary of key points and recommendations: Potential risks of diving

- *General risks:* Panic, hypothermia, physical trauma and drowning.
- *Equipment/technique problems:* Hypoxia, hyperoxia, or poisoning by inappropriate gas mixtures or contaminant gases may result from equipment malfunction or poor dive planning. A malfunctioning respiratory regulator may result in aspiration.
- *Barotrauma:* It is caused by compression or expansion of gas-filled spaces during descent or ascent, respectively. Compression of the lungs during descent may lead to alveolar exudation and hemorrhage. Expansion of the lungs during ascent may cause lung rupture leading to pneumothorax, pneumomediastinum and arterial gas embolism.
- *Decompression illness:* It may occur when gas, which has dissolved in tissues while at depth, comes out of solution as bubbles. Clinical manifestations vary, the most severe being cardiorespiratory and neurological.
- *Loss of buoyancy control:* It is a cause of many accidents, usually when it leads to rapid uncontrolled ascent. It is also essential to consider comorbidities, such as diabetes and epilepsy, which may influence capability for diving, but are outside the scope of this document.

The physician should bear the following general concepts in mind when assessing respiratory fitness to dive:

- The subject may be required to swim in strong currents.
- The subject may be required to rescue a companion (dive buddy) in the event of an emergency.
- The diving environment is associated with a risk of lung rupture.
- The gas breathed by the diver may be very cold.
- Buoyancy control is essential and requires training, experience, and use of appropriate equipment. The following recommendations are therefore made.

BAROTRAUMA

Pulmonary Barotrauma (PBT)

Recalling that gas volume inversely decreases with pressure (and expands with decreasing pressure), it follows that gas containing organs are subject to marked changes in volume. If gas in these spaces is unable to escape, then these organs are at the risk of injury, so called barotraumas.[30,34]

Pulmonary barotrauma is the most life-threatening form of barotrauma and is the second leading cause of diving-related deaths.[27-29,34] The expansion of gas within the lung during ascent can rupture alveoli resulting in air in the interstitium that travels along the perivascular sheaths.[48-50] This would create entry to the mediastinum (mediastinal emphysema), pleural space (pneumothorax), and subcutaneous space (subcutaneous emphysema), or into circulatory system resulting in an

TABLE 105.3: Summary of key points and recommendations: Assessment of respiratory fitness to dive

- In the history, particular attention should be paid to current respiratory symptoms, previous history of lung disease, including childhood history, previous trauma to the chest, and previous episodes of pneumothorax.
- Respiratory system examination should be performed.
- Forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and peak expiratory flow rate (PEF) should be measured. FEV_1 and PEF should normally be greater than 80% of predicted and the FEV_1/FVC ratio greater than 70%.
- Routine chest radiography is not considered necessary in asymptomatic subjects with no significant respiratory history and normal examination findings. However, all professional divers, including recreational divers, who plan to work as instructors are recommended by the health and safety executive to undergo prior chest radiography.
- Chest radiography is appropriate if there is a previous history of any significant respiratory illness—for example, pleurisy, pneumonia, recurrent respiratory infections, sarcoidosis, chest surgery or trauma, pneumothorax—and in those with current respiratory symptoms and/or abnormal examination findings.
- Routine measurement of the expiratory flow-volume loop, exercise testing, or bronchial provocation testing are not considered necessary although these tests may be useful in specific cases.
- Thoracic CT scanning, which has greater sensitivity than standard chest radiography to detect lung structural abnormality, may be useful in specific cases.

AGE.[51,52] Since, pressure and volume changes are near instantaneous, it stands to reason that the clinical presentation for PBT is rapid and may occur while decompressing or soon after surfacing. The most common symptoms with PBT are cough, chest pain and hemoptysis.[51,52] Often the chest pain is noted laterally, but generalized or substernal pain has been also reported. When AGE occurs with PBT, the associated radiographic changes may include alveolar or interstitial opacities, pneumomediastinum, subcutaneous air, intravascular air, pneumothorax, pleural effusion, and retroperitoneal air.[48-52] While no strong evidence supports definite risk factors for developing PBT, some data support that smaller lung volume, less compliance, breath holding, coughing and airway obstruction may put divers at higher risk for PBT.[53-58]

Of the PBT syndromes, mediastinal and subcutaneous air are the most frequent. On auscultation pericardial crunch, known as Hamman's sign synchronous with the heart beat may be heard. A careful chest radiograph examination is required to recognize mediastinal air. If subcutaneous emphysema of the neck area is noted, it is an extension of pneumomediastinum. Though pneumomediastinum is a marker of PBT, and is the most-frequent radiographic finding in AGE, in isolation it generally follows a benign course and may require simple observation.[59,60] Pneumothorax is rare, but potentially devastating, as any trapped air will continue to expand with decreased ambient pressure. Symptoms of pneumothorax may include dyspnea, chest pain, tachypnea, tachycardia, hypotension or cyanosis. On physical examination, distended neck veins, tracheal deviation, hyperresonance to percussion, unilateral decrease in breath sounds are seen; in 20 to 25% of cases, there is associated subcutaneous emphysema. Divers with tension pneumothorax should get a large bore needle insertion into the second intercostal space, immediately followed by tube thoracostomy.[59,60] Divers with airflow obstruction (active asthma, chronic obstructive lung disease), bullae, or cystic lung disease are at high risk for pneumothorax during diving and are advised not to dive.[5,53-58]

Arterial Gas Embolism

In some of the earliest reports, AGE was referred to as submarine lung or compressed air illness in submarine escape trainees (SET). In 1932, Behnke recognized AGE as an air embolism resulting from pulmonary injury.[61] The remarkable clinical presentation of AGE is seen immediately upon or within the first few minutes of surfacing from the dive.[62] Loss of consciousness was noted in 81% of the cases; when coma was the presenting feature, it was seen within 30 seconds of surfacing. In nearly one-third of AGE, chest pain, irregular breathing or apnea and vomiting were noted. Weakness or paralysis, hemoptysis, sensory loss, cardiac arrest, confusion, headache, vision change were noted in 15 to 25% of cases. Less than 10% of the cases reported symptoms of dizziness, dysarthria, ear pain, nausea, dyspnea, ataxia, abdominal pain, diffuse joint pain, and retro-orbital pain were reported.[42]

The presentation of AGE in recreational divers is similar to that of SET, but the clinical course is different because recreational divers are usually not close to a recompression facility; loss of consciousness, stupor or confusion are frequent. Other symptoms often include seizures, vertigo, visual disturbances and sensory changes.[63] Many of the sport diving symptoms often resolve before treatment is initiated. A 2–12 hours treatment delay postembolization has not been associated with an increase in residual neurologic changes.[64] In sport divers AGE is frequently attributed to breath-holding when a diver runs out of air or with buoyancy challenges during ascent. Sport divers may present a combination of clinical features from AGE and DCS. A severe form of spinal cord DCS referred to as "biphasic decompression sickness" may occur; initial presentation being coma and hemiparesis, which improve with breathing oxygen prior to recompression treatment. This initial phase is then followed by a second phase during the recompression treatment with spinal cord manifestations, such as the bladder and bowel dysfunction or paraparesis. Divers with biphasic illness generally do poorly with further hyperbaric treatment. Injured divers may also manifest clinical features of near drowning, such as hypoxia, hypotension and acidosis. These findings further complicate the clinical course of AGE.[62-68]

There is limited human data of AGE as it is rare and in all cases should be treated with rapid recompression therapy. However, animal studies demonstrate air from barotrauma entering the arterial system via the pulmonary vasculature (resulting in focal ischemia), systemic and cerebral vascular systems. Systemic hypertension is noted and this may be secondary to a reflex mechanism.[66] An increase in cerebral blood volume may occur with a rise in intracranial pressure and compromise autoregulation of cerebral perfusion. These changes lead to further increase in cerebral blood volume. EEG changes and evoked potential changes are noted after AGE.[49] Interruption of normal cerebral blood flow and glucose metabolism increases lactic acid production, a major contributor to cerebral infarction. Sudden death in AGE is most likely from ventricular arrhythmias and hypotension from either arterial embolization to the cerebral circulation or the coronary arteries.[68-70] AGE is primarily a clinical diagnosis and should always be treated expeditiously.

Audiovestibular/Sinus and Dental Barotrauma

Since, a closed gas-filled cavity is necessary for barotraumas, it stands to reason that the most frequently involved organs include the ear, nose and throat system. Ear barotraumas during descent occur when middle ear pressure does not equilibrate with the ambient pressure due to Eustachian tube obstruction; this leads to the exudation of fluid, bleed or rupture of the tympanic membrane.[34,71-73] Symptoms of inner ear barotrauma include a sensation of pressure, pain or hearing loss that may resolve. Tympanic membrane rupture during diving may lead to nausea, vertigo and disorientation. Divers are trained to prevent ear barotraumas by using maneuvers to keep the Eustachian tubes open. Treatment of ear injury includes decongestants, analgesics and, if infection occurs, antibiotics.[34,71,72] While middle ear injury is common, inner ear injury is rare, but may lead to persistent vestibular deficits.[73] Treatment of inner ear includes injury bed rest and head elevation, may require tympanotomy and (if necessary) patching of the round window.[55]

Like ear barotrauma, sinus barotrauma may occur during descent or ascent. Descending injuries include mucosal swelling and inflammation causing sinus ostial blockage leading to headache, epistaxis and pain. Topical and systemic decongestants are effective treatments. In extreme cases, ascension injury may result in sinus rupture and pneumocephalus.[34,74,75] Dental barotraumas may occur in infected tooth areas, or around fillings resulting in pain or breakage.[76]

NITROGEN NARCOSIS

The impairment of intellectual and neuromuscular performance and behavioral changes may occur from an increased partial pressure of nitrogen in the nervous system. This syndrome is known as nitrogen narcosis and is often seen at depths of 100 feet or greater. Hallucinations and loss of consciousness have been reported from nitrogen narcosis at depths beyond 300 feet. Risk factors for nitrogen narcosis include hypercapnia, fatigue, hypothermia and alcohol consumption. A compromised mental status at depth is particularly dangerous as judgment errors may quickly result in drowning.[4,77]

PULMONARY EDEMA

Pulmonary edema in scuba divers is rare, but has been reported. Though the etiology of pulmonary edema in divers is not clear, it is known that water immersion significantly increases intrathoracic fluid. This volume increase may combine with heavy exercise, hydration and peripheral vasoconstriction to cause failure of the pulmonary capillary bed. This condition may be associated with cough, hemoptysis and dyspnea. Findings of pulmonary edema are noted on physical examination and radiography (Fig. 105.3). Generally, this syndrome resolves with supportive care in a short period of time.[78-82]

TREATMENT OF DECOMPRESSION DISORDERS

There has been remarkable effort put forth to prevent and treat decompression illness resulting in the decreases of diving accidents and increases in effective treatments.

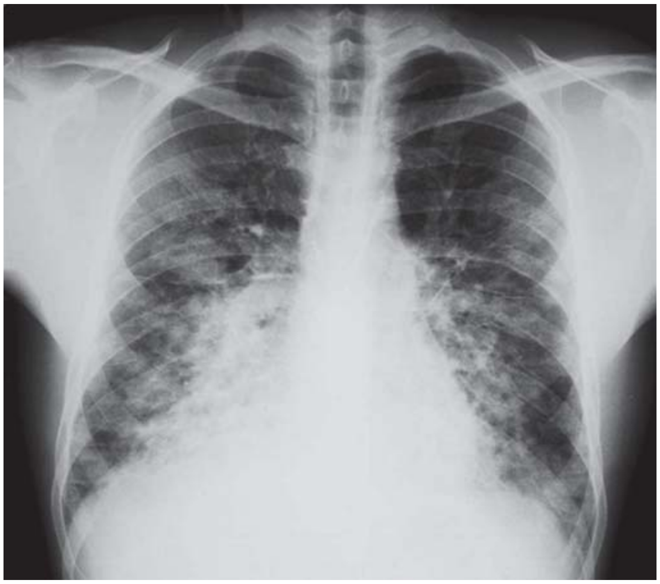

Fig. 105.3: Immersion pulmonary edema

In the last five to six decades, major advances have been made in training, technology and preventive education along with the development of standardized treatment tables. Prior to these recent advancements, DCS treatment since the mid-nineteenth century consisted of recompression with air. Today's improved treatment modalities have significantly improved the clinical outcome.

A thorough history and physical examination is critical to any decision on DCS treatment. The history should include detailed information on the clinical symptoms, the onset and progression (or regression) of symptoms, depth and duration of diving exposure, presence or absence of barotraumas and any underlying illness prior to diving. Symptoms of neurological DCS manifest within the first 10 minutes of surfacing in more than 50% of the cases; more than 90% within the first three hours.[83] Pain manifestation of DCS may have a much longer onset, up to 6 hours or more, particularly after saturation dives. Symptoms occurring prior to decompression (at depth) are often due to barotraumas, gas contamination or other extraneous injury. The differential diagnosis of DCS includes other causes, such as myocardial infarction, environmental toxins, or other neurologic diseases not recognized prior to the dive. Psychiatric illnesses and factitious disorders should also be kept in mind.[84,85]

If divers experience only pain on surfacing, it is usually not accompanied by any physical findings, such as joint swelling or redness. Skin manifestations may include a macular or pruritic rash. Skin changes that involve deeper layers with lymphedema are referred to as cutaneous marmorata. Despite advances in imaging techniques for CNS, the most reliable tool for treatment and follow-up in DCS is the clinical assessment. Abnormalities of gait, especially when assessed with a tandem gait test, denote an early specific feature; however, they are often out of proportion to motor and sensory changes. Sensory changes, if present, are patchy and have a nondermatomal distribution. Multiple levels of neurologic manifestations affecting cerebrum, brain stem, spinal cord, and peripheral nerves may be seen.[86-88] Dyspnea, tachycardia and hypotension indicate the critical nature of DCS and are often due barotraumas and AGE.

In general, imaging studies are not useful in the initial evaluation of DCS. However, chest radiograph can identify pulmonary barotraumas, such as the mediastinal air, subcutaneous emphysema or pneumothorax. Divers are at risk for drowning, aspiration and pulmonary edema, which may be evident by radiograph. Diffuse capillary leak from gas embolism may present with Acute Respiratory Distress Syndrome (ARDS)/pulmonary edema changes on chest radiograph.[86,89]

Neuropsychological, electrophysiological testing (such as the electrophysiology [EEG]) and somatosensory evoked potential have not been clinically useful in the assessment and the management of neurological DCS, especially in the pretreatment phase, and would likely serve only to delay therapy.

Initial Stabilization

Initial stabilization of airway patency, breathing and circulation should be addressed in all divers who manifest with DCS. Initiating treatment with supplemental oxygen, fluid replacement and chest tube drainage if pneumothorax is noted, are initial stabilization considerations. In suspected AGE, head-down position is recommended to minimize the risk of cerebral embolization without increasing the risk of cerebral edema. Oxygen supplementation is preferred via face mask to provide 100% FiO_2 en route to recompression therapy. In the case of air medical evacuations, the lowest safe altitude should be maintained so as not to contribute more to the decompression stress. Recompression treatment is recommended for all divers with neurologic, cardiopulmonary and some joint manifestations of DCS as it seems to provide some beneficial prognostic advantage. Given the overall safety of recompression therapy, a general low threshold for its implementation is routine and in some circumstances, may add diagnostic utility.[22,26-29,34]

Recompression

The management of DCS involves returning the diver to pressure and the use of Hyperbaric Oxygen (HBO); so called recompression therapy. The return to pressure "crushes" the existing bubbles and the HBO enhances the washout of inert gas and enhances oxygen delivery to tissue beds. Several treatment strategies, known as treatment tables, are used, but the most common is the United States Navy's treatment table 6 (TT6). The Navy TT6 uses HBO at 2.8 ATA with short periods of air to minimize oxygen toxicity.[22,26-29,34]

Early hyperbaric therapy is recommended, however there is no time limit beyond which the recompression has been determined to be not efficacious. This is important because recreational divers may have limited access to recompression therapy. Treating diving-related injuries requires clinical expertise and certified personnel for the safe operation of a hyperbaric chamber (Figs 105.4 and 105.5). Hence, it is recommended (and in some cases regulated) that personnel with experience and expertise initiate and treat DCS.

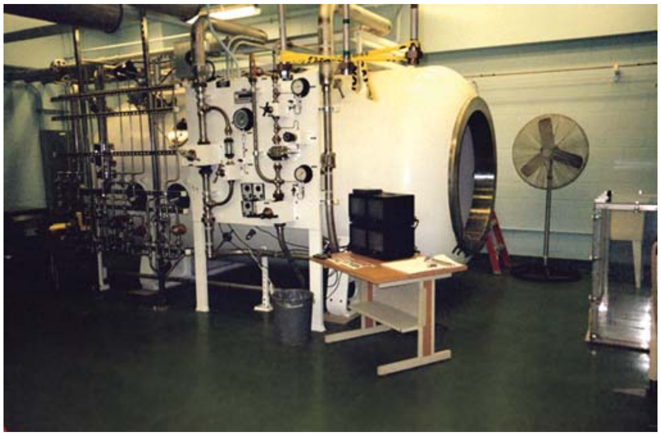

Fig. 105.4: Hyperbaric chamber-outside

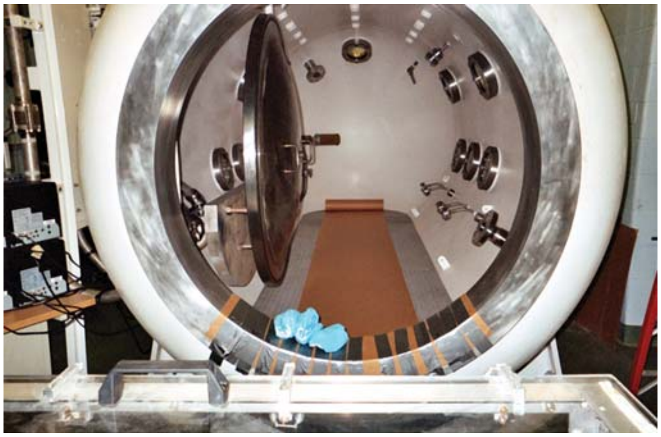

Fig. 105.5: Hyperbaric chamber-inside

If the resolution of DCS symptoms is incomplete after a single hyperbaric treatment, further hyperbaric treatments may be used once or twice daily until there is resolution of symptoms, or no further improvement is observed. Most require one to two treatments. Rarely with severe neurologic DCS, up to 20 treatments have been completed. Adjunctive measures to hyperbaric treatment for DCS include intravenous fluid administration; use of corticosteroids and indomethacin are of limited value. There is reasonably strong evidence to support the use of lidocaine as it appears to preserve blood flow to the brain, reduce cerebral edema and infarct size, and reduce intracranial pressure.[88-92]

Return to Diving after Diving Injury

Pulmonary barotrauma is an uncommon event and generally, chest radiographs and CT scans have not been useful in predicting barotrauma risk. Similarly, spirometric and compliance evaluations have not been uniformly helpful in assessing barotrauma risk. However, physicians consider a prior diving-related barotrauma as a high risk for recurrence and many recommend CT scans of the chest to look for parenchymal and pleural abnormalities.

Return to diving depends on the residual neurologic damage and dysbaric osteonecrosis. A minimum one month delay after a DCS event is recommended before the next dive. In non-recreational divers with DCS, those that were successfully treated with a diving treatment table 5 can return to diving after 7 days; those that required a Treatment table 6 should return only after 4 weeks and after a dive clearance by a physician trained in diving medicine.[93,94]

LONG-TERM EFFECTS OF DIVING

Divers are exposed to acute changes, but may also have long-term effects from diving.[95] This chapter previously described some factors that might put a diver for acute adverse events. Table 105.4 summarises the key points and recommendations of diving with specific respiratory conditions. Some environmental factors encountered during diving, as well as the impact of DCS and AGE, have the potential for long-term effects on different organ systems (Table 105.5).

Effects on Lung

Ambient pressure, duration and breathing gas mixture may have a direct impact on lung function. Other factors

TABLE 105.4: Summary of key points and recommendations: Specific respiratory conditions

- Lung bullae or cysts increase the risk of barotrauma and are contraindications to diving.
- Previous spontaneous pneumothorax is a contraindication unless treated by bilateral surgical pleurectomy and associated with normal lung function and thoracic CT scan performed after surgery.
- Previous traumatic pneumothorax may not be a contraindication if healed and associated with normal lung function, including flow-volume loop and thoracic CT scan.
- Subjects with asthma should be advised not to dive if they have wheeze precipitated by exercise, cold, or emotion.
- Subjects with asthma may be permitted to dive if, with or without regular inhaled anti-inflammatory agents (step 2 of the BTS guidelines 4), they:
- Subjects are free of asthma symptoms;
- Subjects have normal spirometry (FEV_1 >80% predicted and FEV_1/VC ratio >70% predicted); and
- Subjects have a negative exercise test (<15% fall in FEV_1 after exercise).
- Subjects with asthma should monitor their asthma with regular twice daily peak flow measurement and should refrain from diving if they have:
- Active asthma—that is, symptoms requiring relief medication in the 48 hours preceding the dive;
- Reduced PEF (more than 10% fall from best values); increased peak flow variability (more than 20% diurnal variation).
- COPD carries a theoretical increased risk of barotrauma and reduced exercise tolerance. Subjects will probably be advised against diving on the basis of reduced pulmonary function (FEV_1 <80% predicted).
- Sarcoidosis has been associated with pulmonary barotrauma. Diving is contraindicated in subjects who have active sarcoidosis. Those in whom sarcoidosis has resolved should have normal chest radiography and pulmonary function testing before being advised that they may proceed with diving.
- Tuberculosis is a potentially transmissible disease that may cause residual impairment of lung structure and function. A subject with active tuberculosis should not dive. After curative treatment they may dive if lung function and chest radiograph are normal.
- Cystic fibrosis is often associated with abnormal pulmonary function and the increased risk of pneumothorax. Diving is contraindicated in those patients who have pulmonary involvement.
- Fibrotic lung disease reduces lung compliance and impairs gas transfer. Diving is therefore contraindicated in subjects who have fibrotic lung disease.

TABLE 105.5: Long-term effects of diving on the lung

- Divers tend to have large lung volumes with proportionately greater increases in vital capacity than in FEV_1. This may be attributable in part to the effects of repeatedly breathing dense gas through increased resistances.
- Divers may have reduced expiratory flow rates at low lung volumes, possibly reflecting small airway disease.
- Vital capacity of divers may decline with age at an increased rate.
- Saturation diving causes a fall in carbon monoxide transfer, which once the dive is completed, gradually returns to predive values.

that may indirectly affect lung function include DCS, gas bubbles in pulmonary vasculature, breathing effort, respiratory heat/cold, dehydration and contaminated water exposure. Clearly, individual diver's Vital Capacities (VC) is important. Divers have been reported to have vital capacities larger than predicted.[96,97] Generally, there was an initial increase in VC until the age of 30, at which point it declined. It was found that the Forced Expiratory Volume in one second (FEV_1) the most frequently used index for assessing and quantifying airflow limitation, did not increase proportionately resulting in a lower than predicted FEV_1/FVC ratio. An international consensus conference concluded that there is evidence to suggest changes in bone, lung, and central nervous system in some divers who had not experienced a diving accident or exposure to environmental hazards.[95]

Dysbaric Osteonecrosis

Grützmacher in 1941 first reported osteonecrosis in a diver even though it had previously been observed in tunnel and caisson workers.[98] Dysbaric Osteonecrosis (DON) is often seen in the humeral head as against femoral head in other nontraumatic osteonecrosis. Osteonecrosis develops when decompression after hyperbaric exposure produces gas bubbles in fatty bone marrow expanding the adipocytes. This can lead to local and disseminated intravascular coagulation and intraosseous thrombosis along with platelet aggregation, lipid emboli, and the release of vasoactive substances. DON is most common in native diving fishermen who perform routine, repetitive diving for livelihood over many years.[99,100] Shinoda and associates detected DON in all 23 divers who underwent Magnetic Resonance Imaging (MRI) exam of shoulders, hips and knees. They also demonstrated a correlation between the diving depth and DON severity in the humerus.[101] DON is reported rarely in recreational scuba divers.[102] Risk factors for DON are obesity and alcohol abuse, cigarette smoking, fatty liver, hyperlipidemia, and impaired fibrinolysis.[103] Alcohol-induced osteonecrosis has been reported in nondivers.[104]

CNS

Diving-related events, such as DCS and AGE result in acute injury, but may also have adverse long-term outcomes to the spinal cord and brain. There are also concerns regarding possible CNS effects in divers who never experience DCS or AGE. Many studies have used psychometric testing, MRI and other imaging modalities to assess CNS function in divers who never suffered AGE or DCS. In general, no significant or progressive disability has been noted. However, in those who have suffered DCS with spinal cord injury, nearly 10% have sustained permanent gait changes and were unable to return to work. Also, those who had significant cerebral DCS were found to have permanent impairment, such as poor concentration, memory deficits and headaches that were correlated with imaging abnormalities. Saturation and commercial divers examined have not shown any sustained brain function impairment.[104,105]

Morbidity and Mortality in Scuba Diving

DAN publishes an annual report of diving-related accidents, injuries and mortalities. However, a true incidence based on these numbers is difficult to ascertain. The common morbidities result from running out of air underwater, rapid ascent and drowning. DAN reports that 6 to 14% of fatalities were of cardiovascular origin, and 5 to 14% from air embolism. A medical screening is required prior to scuba training, but the physical standards, which are required, vary among countries. Scuba training emphasizes safety: Proper use of equipment, controlled ascents, decompression stops, adequate air supply checks, etc.

SUMMARY

Over its long history, diving has been used primarily for the commercial and military operations. However, over the last few decades, the popularity of diving as a recreational activity has grown steadily. The technical aspects of diving have evolved over the years to allow the deeper diving of longer duration in challenging locations. Diving requires specialized training and is associated with multiple risks. Physical fitness is an essential requirement for training and many training centers also require medical clearance for diving certification.

The authors are very grateful to Ms Diana Temple for her editorial assistance of the manuscript.

“No financial or other potential conflicts of interest exist for the above authors. The views expressed in this article are those of the authors and do not reflect the official policy or position of the Department of the Navy, Department of Defense, or the United States Government. I/We certify that all individuals who quality as authors have been listed; each has participated in the analysis of data, the writing of the document, and the approval of the submission of this version; that the document represents valid work; that if we used information derived from another source, we obtained all necessary approvals to use it and made appropriate acknowledgements in the document; and that each takes public responsibility for it. APPENDIX: SIGN LEVELS OF EVIDENCE AND GRADING OF RECOMMENDATIONS

Levels of Evidence

Ia: Evidence obtained from meta-analysis of randomized controlled trial.
Ib: Evidence obtained from at least one randomized controlled trial.
IIa: Evidence obtained from at least one well designed controlled study without randomization.
IIb: Evidence obtained from at least one other type of well designed experimental study.
III: Evidence obtained from well designed nonexperimental descriptive studies, such as comparative studies, correlation studies and case-control studies.
IV: Evidence obtained from expert committee reports or opinions and/or clinical experience of respected authorities.

Grading of Recommendations

A (Levels Ia, Ib): At least one randomized controlled trial as part of the body of literature of overall good quality and consistency addressing the specific recommendation.

B (Levels IIa, IIb and III): Requires well conducted clinical studies, but no randomized controlled trial on the topic of recommendation.

C (Level IV): Requires evidence from expert committee reports or opinions and/or clinical experience of respected authorities. Indicates absence of directly applicable studies of good quality.

Lung Diseases in Coal Workers

Harakh V Dedhia, Daniel E Banks

INTRODUCTION

Coal is not a pure mineral. It is formed by the accumulation of vegetable matter covered by sedimentary rock (thereby sealing it from air) and subjected to pressure and temperature over the ages. This causes the physical and chemical properties of the matter to change. The matter dries, becomes warmer and loses oxygen content, all the while increasing the relative carbon content.[1]

The first step in this conversion of vegetable matter to coal is the formation of peat, a moist spongy material. This transformation of organic deposit can occur in a stagnant water bed relatively quickly (at a rate of approximately one foot per 100 years). An approximately 100-foot accumulation of peat compresses to form a one foot wide coal seam. In the simplest terms, coal is comprised of moisture (which lessens with time), pure coal (carbon) and mineral matter.[2]

The process of conversion (coalification) from organic matter follows a transformation of wood to peat to lignite to bituminous coal to anthracite coal (Table 106.1).[3] The terms “brown coal” and “black coal” refer to the coals of low and high rank, respectively. Rank describes the extent of change from vegetation to mineral-free coal.

The composition of coal mine dust varies with the coal seam. Most of the dust is composed of carbon, although in some seams it may only approximate 60% of the dust, with more than 50 different elements and their oxides.[4] Dusts of high rank typically have more silica than the dusts of lesser rank because the anthracite seams often have roofs and floors of quartz, which contaminate the coal during mining. Although the amount of coal mined yearly continues to increase, coal continues to decline in its importance as a world energy source, while petroleum and natural gas are increasingly used as substitutes. In addition, a byproduct of burning coal is carbon dioxide, a greenhouse gas and a major source of concern with respect to changes of the global climate.

In the US, electric power generation accounts for the utilization of more than 80% of the coal produced each

TABLE 106.1*: Coal characteristics

Coal rank	*% volatile matter*	*% carbon*	*% ash*	*% moisture*	*BTU**/pound*
Peat (dried)	70	25	5	10	8,000–12,000
Lignite	41	36	9	14	5,500–7,000
Bituminous	32	55	10	3	12,000–14,000
Anthracite	5	87	5	3	> 13,000

**One BTU (British thermal unit) is equivalent to the amount of heat necessary to raise the temperature of one pound of water from approximately 4º to 5º F.

year. In India, like in the US, coal production yields approximately half of the country's energy needs.[5] The country's industrial heritage has been built upon indigenous coal. Commercial primary energy consumption in India has grown by about 700% in the last four decades, and in the face of a rising population and expanding economy, this is likely to continue. With the relatively limited amount of petroleum and natural gas, the restrictions placed on the development of hydroelectric projects and the political disagreements associated with nuclear power, coal will remain in the forefront of India's energy structure. India's proven hard coal reserves are estimated to be 92 billion tons (with three or four more times this amount likely). These deposits are recognized to be dispersed over 27 major coalfields, mainly in the eastern and south central parts of the country. Lignite, or soft coal, reserves approximate 36 billion tons, the great majority located in the southern state of Tamil Nadu.[6]

Epidemiologic Features of Coal-Induced Lung Disease

The current system of classifying the radiological severity of pneumoconiosis began with the work of Davies and Mann.[7,8] These investigators postulated that the number of small opacities visualized on the chest radiograph reflects the severity of pneumoconiosis and introduced the concept of the "major" categories of simple pneumoconiosis (based on the profusion and extent of opacities). Liddell is later credited as the first to divide each major category into three subcategories.[9] These notions were incorporated into the International Labour Organization (ILO) 1958 classification of the radiographs of pneumoconioses, in which a continuum of the profusion of opacities is separated into four distinct categories—from 0 to 3.[10] The next steps were to relate these standardized abnormalities on the chest radiograph to spirometric and demographic data.

The International Union Against Cancer (UICC) Working Group on Asbestos and Cancer in 1964 recognized the need to improve comparability and build on this classification.[11] Further changes of this scheme form the basis of what is the basically the current ILO system, initially introduced as the 1970 UICC/Cincinnati classification.[12] These included the division of pleural changes into "calcified" and "noncalcified", as well as changes in the manner that small opacities were described. A 12-point scale reflecting a series of "shades of gray" within a major category was added. In addition, the lung was separated into three zones for more descriptive imaging, rather than characterized as a single entity, and small opacities separated into "rounded" and "irregular" shapes, and then further separated small opacities into different sizes ('p', 'q', 'r' and 's', 't', 'u'). Copies of "standardized" radiographs were made available from several investigators. The 1968 ILO classification system was a modification to incorporate asbestos-related diseases based in part on the UICC/Cincinnati classification system.

The 1980 ILO classification system made several more refinements. These included a set of 22 standard chest radiographs (available to all interested parties), which were examples of the size, shape and profusion categories of opacities. An estimate of film quality became a part of the protocol and the description of the pleura was more detailed.[13] In 2000, the ILO gave the scheme it's most recent "face lift." Standard films illustrating "u" shape shadows and pleural abnormalities were changed. Film quality was now judged on a scale from unimpeachable (+) to unusable ("u"). If not "+", then written comments are needed. Obliteration of the costophrenic angle was necessary for "diffuse pleural thickening." New symbols for chest radiological findings were also included.[14,15,16] Although the chest radiograph is the foundation for the diagnosis of Coal Workers' Pneumoconiosis (CWP), it may be insensitive at low profusion of macules and nodules.[17,18] In this setting, High Resolution Computed Tomography (HRCT) scanning may be more informative.

CLINICAL FEATURES OF COAL DUST EXPOSURE

Coal inhalation can result in industrial bronchitis and CWP, presenting as either simple pneumoconiosis or as complicated CWP or Progressive Massive Fibrosis (PMF).

Industrial bronchitis is a common diagnosis among workers exposed to dusts, including coal dust.[19] It manifests as a productive cough, which persists for at least three months per year for at least two years (chronic bronchitis) associated with workplace dust exposure. In a defining autopsy study, coal dust exposure resulted in an increase in the maximal gland: wall ratio (independent of smoking), but no relationship between mucous gland size and the amount of lung dust or presence or absence of pneumoconiosis was found.[20] These data suggest that mucous gland enlargement is related to the inhalation of larger (non-respirable) dust particles, which present a chronic burden to the mucociliary escalator and act as irritants to the airway, whereas pneumoconiosis is related to respirable dust exposure with the internalizing of these particles into the lung interstitium.

Early reports showed that the prevalence of bronchitis in coal miners varied by smoking history, age and job.[21] In all reports, smoking miners had bronchitis more frequently than nonsmokers, and when studied, showed bronchitis to increase with age (a surrogate for years of dust exposure in the workplace). Marine identified 543 lifetime nonsmokers among 14,888 British coal miners (3.6%) studied between 1953 and 1967 who were less than 65 years of age, worked at the coal face in most instances, did not have PMF, and who had participated in three surveys over 10 years.[22] Of these, 17% had bronchitis at the third survey. In a second report of coal miners, 16% had bronchitis.[23]

Coal workers' pneumoconiosis results from the inhalation and deposition of coal mine dust, and the lung's reaction to its presence. Three criteria are necessary for this diagnosis.[24] They include:

1. A chest radiograph consistent with the features of CWP;
2. A work history (typically underground coal mining) sufficient in exposure and latency to result in pneumoconiosis; and
3. The absence of other illnesses which may mimic CWP.

Therefore, the diagnosis of CWP can be made with confidence without histologic confirmation. Clinical features, such as dyspnea, cough and sputum production are important in addressing the degree of a miner's impairment, but are not a part of the diagnostic criteria. The radiographic appearance of CWP cannot be differentiated from silicosis, and coal miners may develop disease from exposure to both dusts.

Coal workers' pneumoconiosis is categorized as simple pneumoconiosis or PMF. The radiograph in simple pneumoconiosis shows small opacities, ranging in size from pinhead to 1 cm in diameter. Rounded nodules predominate and tend to appear first in the upper zones and then the middle and lower zones as the number of opacities increase. With prolonged excessive exposure, these small opacities may coalesce and form larger opacities, typically in the upper zone, recognized as PMF lesions and characterized by one or more large opacities greater than 1 cm in diameter. Associated distortion of lung architecture typically includes the deviation of the trachea and major airways to the side of the most prominent area of coalescence, loss of upper zone lung volume, elevation of the hila, and basilar emphysema (typically of a panacinar type), attributable to traction placed on the lower lung zones by the elevation of the hila. Importantly, CWP can progress after the cessation of coal mine dust exposure.[25]

In a population comparing miners without CWP to those with CWP, respiratory symptoms and physical signs were no more prevalent in those with simple CWP.[26] The not infrequent presence of a chronic cough and sputum production, even in the presence of CWP, is reasonably attributable to "industrial bronchitis." Alternatively, these same clinical features in a smoking miner may be partially attributable to bronchitis caused by the inflammatory stimulus of cigarette smoke. Finger clubbing is not a feature of CWP, and if noted, should prompt further investigations. Yet, when PMF is recognized on the chest radiograph, the worker frequently describes dyspnea, cough and sputum production, although it is recognized that the degree of impairment and presence or absence of symptoms does not correlate well with the extent of chest radiographic abnormalities.

The effect of pneumoconiosis on the heart has been described by several investigators. Lapp performed cardiac catheterization during rest and exercise in miners with CWP, some with airways obstruction.[27] Those with underlying obstructive lung disease or PMF had increased pulmonary artery pressures. In those without these two illnesses, increased pressures occurred in the presence of pinpoint (p) opacities on their radiograph. This type of opacity is associated with diminished diffusion and a decreased vascular bed.[28] A later autopsy study of British coal miners addressed the relationship between coal dust exposure and Right Ventricular Hypertrophy (RVH) comparing those with simple CWP or no pneumoconiosis to those with PMF. The prevalence of RVH was the same in those with simple CWP as in those without pneumoconiosis (approximately 15%) and was related to the extent of airways obstruction. Right ventricle enlargement did not occur unless the miner was a smoker with severe airflow obstruction or PMF.[29]

Typically, CWP is a slowly progressive illness, with radiographic features progressing over a period of many years. The appearance of a cavity in a PMF lesion or an aggressive rate of radiographic progression should prompt the examination of the sputum for mycobacterial infection. The chest radiograph in simple CWP correlates with the amount of dust in the lung at autopsy.[30] This is not true of the complicated form of the disease, suggesting that inadequately defined host factors play a role in the development of this lesion. Hypotheses which might explain the differences in tissue response to coal dust in those who remain with simple CWP and those who progress to PMF include:

1. Inhalation of significant amounts of silica in addition to coal in mine dust;

2. Infection with an atypical mycobacterial organism; and
3. Development of specific immunologic factors, which are responsible for progression.

Yet, none of these explanations appear to satisfactorily explain the development of PMF. First, PMF has been reported in carbon electrode workers. This suggests that silica exposure is not necessary for PMF to occur.[31] Treatment of miners with simple CWP in Wales with antituberculous drugs did not prevent PMF.[32] Autoantibodies reactive to lung tissue antigens have been demonstrated in the sera of miners suggesting a role in the tissue response.

A special case of nodular lung reaction occurs in dust-exposed individuals who either have rheumatoid arthritis or who develop rheumatoid arthritis within the subsequent 5 to 10 years.[33,34] This leads to discussion regarding the potential role of immunological factors in mineral dust pneumoconioses. The nodules of Caplan's syndrome vary in diameter from 0.5 to 5 cm and are usually multiple, bilateral and situated peripherally. Grossly, the lesions resemble a giant silicotic nodule. Microscopically, the amount of dust in the lesion is small, there is a necrotic area in the center, and there is a surrounding cellular zone infiltrated with lymphocytes and plasma cells. In many nodules there is a peripheral zone of active inflammation with neutrophils and a few macrophages. This observation was further enhanced when similar radiographic appearances in miners without arthritis, but in whom circulating rheumatoid factor was demonstrated. An increased incidence of circulating positive rheumatoid factor among miners with PMF has also been reported. In a group of 60 consecutive cases of scleroderma, Rodnan described 26 cases with a history of employment as a coal miner or employment in an occupation where silica exposure was encountered.[35] Although, the course of scleroderma did not vary in the two groups, it appears that chronic fibrogenic dust exposure may be a risk factor for the development of scleroderma.

The clinician may be presented with the diagnostic dilemma of attempting to distinguish a primary or metastatic neoplasm from an unusual presentation of PMF. When large opacities of PMF occur bilaterally on a background of simple CWP, one can be reasonably confident that the lesions are less likely to represent neoplastic disease. When there is a sparse background of simple CWP or none, or there are crops of nodules (as in Caplan's syndrome), the differentiation from neoplasm may indeed be difficult.[36] Among underground miners (Fig. 106.1), those working at the face and are exposed to higher concentrations of coal mine dust had a higher prevalence of CWP than surface workers (Fig. 106.2) or those whose jobs caused them to enter the face area intermittently.[37]

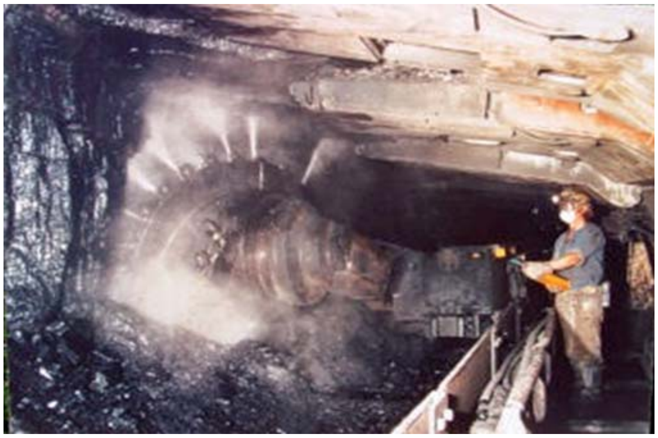

Fig. 106.1: Shows the aggressive aspect of underground mining and how productive this process is. The cutting head is cooled and generated dust limited by the spray. The miner is protected by roof cave-ins by standing under the overhead supports

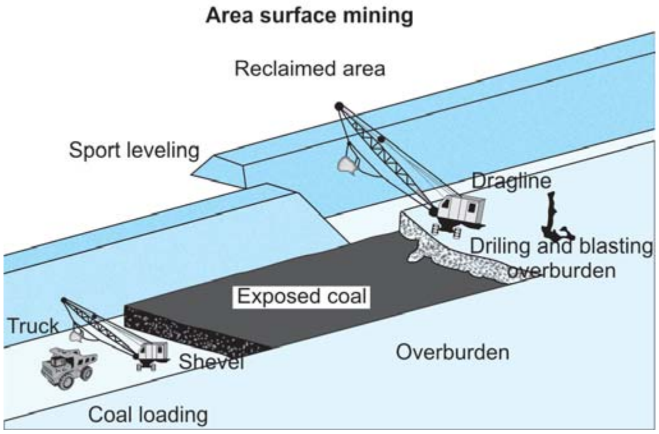

Fig. 106.2: Surface mining mines coal located near the surface. This process requires removing the overburden (earth and rock covering the coal seam) with heavy earth-moving equipment, such as draglines, power shovels, excavators and loaders. Once exposed, miners drill, place explosives charges and fracture the coal. This allows for the systematic removal of coal using trucks or conveyors and the transport to a coal preparation plant

PATHOLOGY OF CWP

As the normal dust clearance mechanisms of the lung are overwhelmed, dust deposition increases. With the

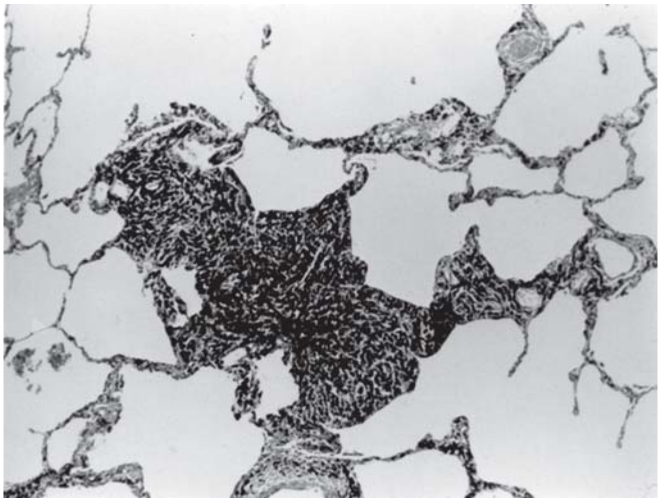

Fig. 106.3: This is a photomicrograph of a coal macule. There is coal dust, reticulin fibers, and coal dust-laden macrophages, with minimal fibrosis. The periphery of the nodule shows air space enlargement

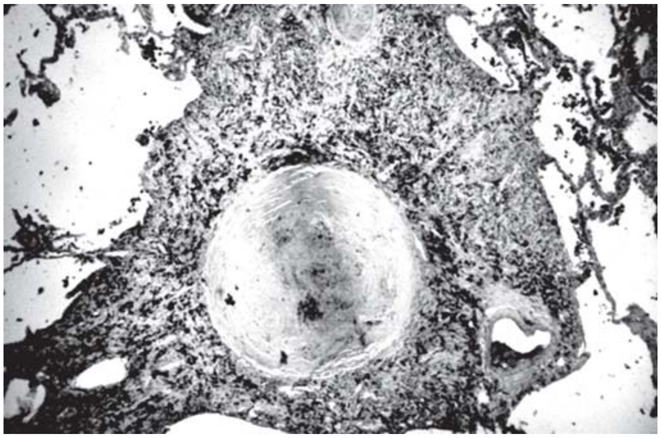

Fig. 106.4: This figure shows a photomicrograph of a lung biopsy from a roof bolter with the histologic evidence of both a coal macule and a silicotic nodule. This reflects the accumulation of coal and silica dusts exposure, which have occurred over his working lifetime. On the periphery, there is coal dust with coal-laden macrophages. Centrally, there are the whorls of fibrosis characteristic of a silicotic nodule. The cellularity is most prominent in the periphery of the lesion

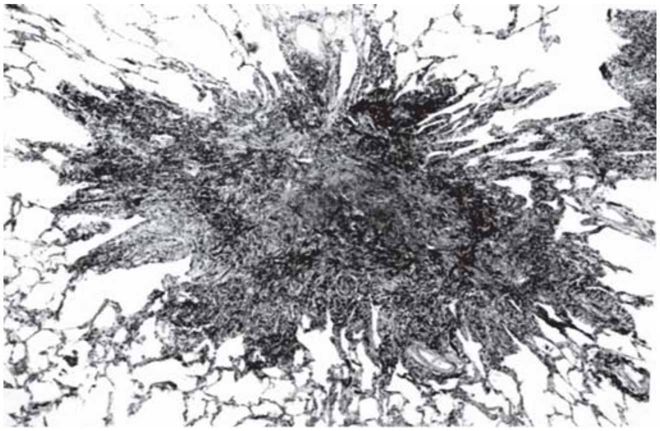

Fig. 106.5: The figure shows a coal nodule surrounding a respiratory bronchiole. As the macule enlarges, smooth muscle atrophies, and the bronchiole enlarges. Of interest in this photomicrograph are the enlarged air spaces surrounding the macule, a feature described as focal emphysema

initiation and progression of fibrosis, the lung lesions increase in size and number. A focal collection of coal dust in pigment-laden macrophages around dilated respiratory bronchioles, which tapers off towards the alveolar duct, is initially apparent.[38] This is the coal macule, the characteristic lesion of CWP (Figs 106. 3 and 106.4).[39,40] A fine network of reticulin within this collection of cells may be visible early on. Focal emphysema is a specific entity that is an integral part of the simple lesion of simple CWP (Fig. 106.5). It is characterized by the enlargement of the air spaces immediately adjacent to the dust macule.[41]

What impact this has on lung function has been the subject of considerable discussion. In nonsmoking, nonobstructed miners, Morgan[42] showed an increase in the Residual Volume (RV) in miners. In miners without CWP, the RV was 105% of a group of nonminers. This increased to 108% and 114% of controls in miners with category 1 or category 2 and 3 simple CWP. Morgan considered that this may be attributable to focal emphysema. He also considered this hyperinflation to be the result of coal macules narrowing the airways with the alteration of the peripheral flow rates by and increasing resistance. On gross examination of the lung, larger collections of dust are described as coal nodules, classified as micronodular, if they are 7 mm in diameter or less and macronodular, if they are larger than this. These are palpable whereas coal macules are not.

Progressive massive fibrosis is diagnosed when one or more nodules attain a size of 2 cm or greater in diameter, typically on a background of simple CWP[43] (Fig. 106.6). The 2 cm diameter is an arbitrary choice of a minimal diameter that has allowed better correlation with clinical and radiographic measurements. In other reports, nodules exceeding 1 cm are included as PMF. Gross examination of the lung in PMF reveals a solid, heavily pigmented lung, which is rubbery-to-hard in texture. These features are most common in the posterior portions of the upper lobes or the superior segments of the lower lobes. These lesions tend to occur asymmetrically, occasionally showing first in one lung and then the other, leading to a suspicion of malignancy. When these

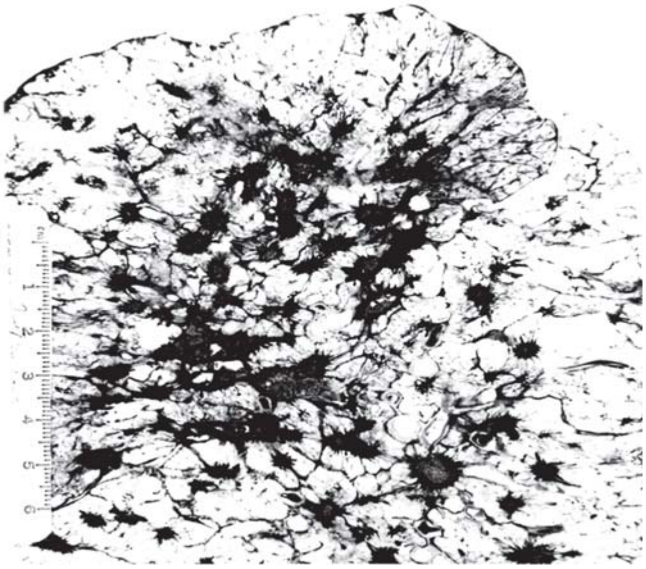

Fig. 106.6: This is a Gough section of the lung. Simple coal workers' pneumoconiosis (category 1) is percent on a background of diffuse emphysema. The black deposits are the coal macules. The degree of emphysema is widespread and does not appear associated with the coal macules

lesions are ashed, they appear to be composed of varying amounts of coal, silica, calcium and other substances. About ¼ of the proteinaceous material in the center of these lesions is collagen.[44] These lesions may also cavitate and the worker may expectorate an ink-like fluid (a clinical sign described as melanoptysis), or when these cavitary lesions are cut, they may drain ink-like fluid. Airways and vessels adjacent to the lesions are distorted and destroyed within the lesions.

Excessive silica exposures in surface coal mine drillers can also result in PMF lesions and result in "cor pulmonale" and respiratory failure (Figs 106.7A to 106.9).

How CWP Develops: Cellular and Immunologic Factors

Coal workers' pneumoconiosis is the result of coal dust-induced cell damage with the activation of the fibrotic process. Lapp provided a well-outlined approach to addressing how coal dust causes lung damage.[45] The potential mechanisms include:

1. Direct cytotoxicity of coal dust;
2. The release of oxidants, enzymes, and cell membrane constituents from Alveolar Macrophages (AMs) in association with cell death due to coal dust exposure; and

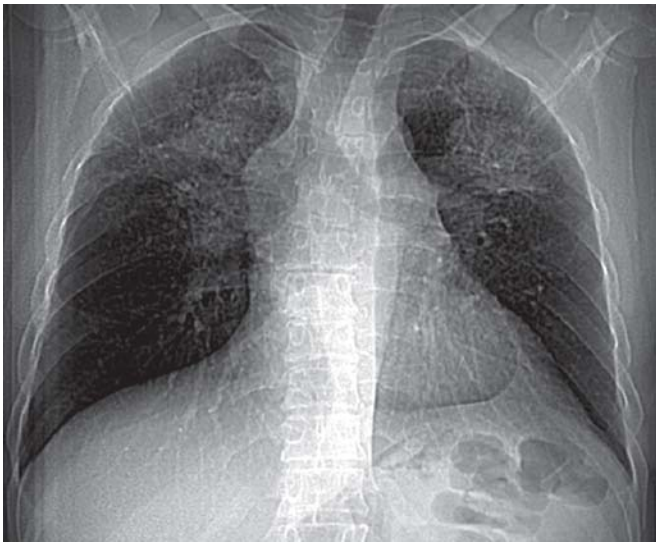

Fig. 106.7A: The figure shows multiple small rounded densities bilaterally, predominantly located in the upper lung zones. Mass-like densities are also present in the upper zones, and the overall appearance is typical for PMF

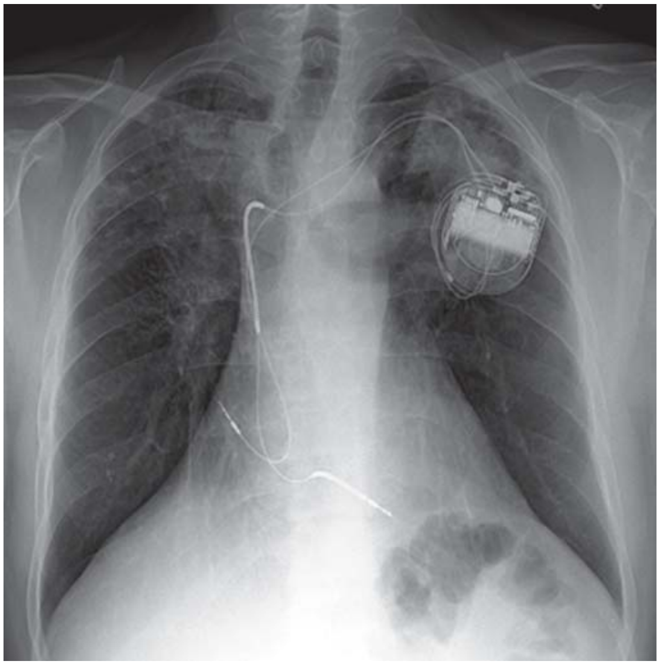

Fig. 106.7B: The picture is taken six years later, it shows progression of PMF over time. In the time between figures 106.8A and 106.8B, a pacemaker-defibrillator with intracardiac 2 leads had been inserted

3. Stimulation of cytokine release from AMs to recruit effector cells (other macrophages or neutrophils) and stimulate fibroblast proliferation and collagen synthesis in the area of coal dust deposition.

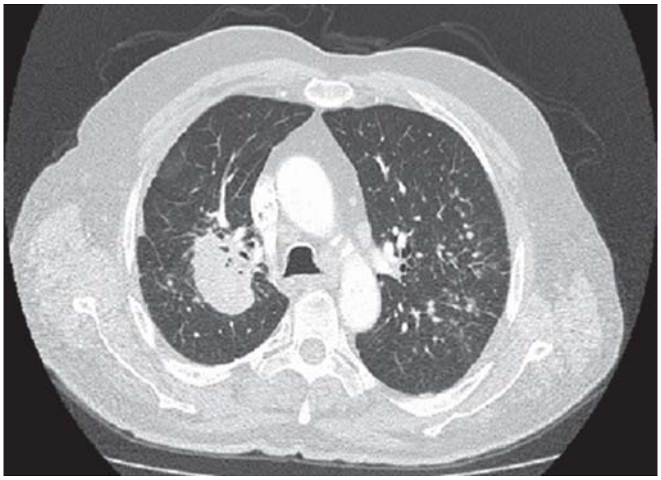

Fig. 106.8A: Chest CT scan in a surface coal mine drillers, which shows bilateral upper lobe fibrosis, more prominent on the right compared to the left, and a RUL mass

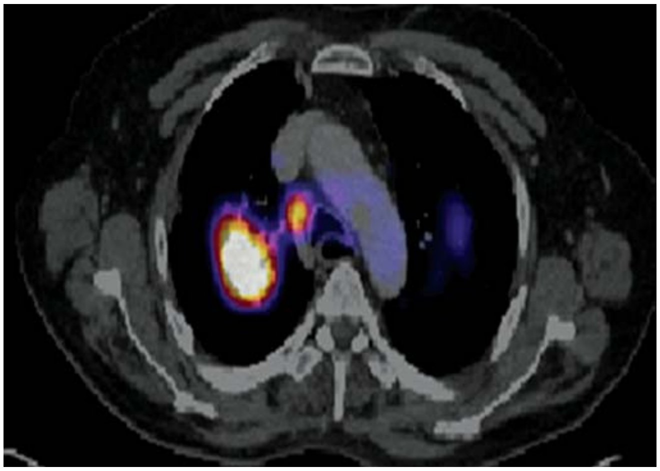

Fig. 106.8B: A PET scan taken near the time of figure 106.8A shows asymmetric PMF lesions (right more than left) as well as right peritracheal adenopathy

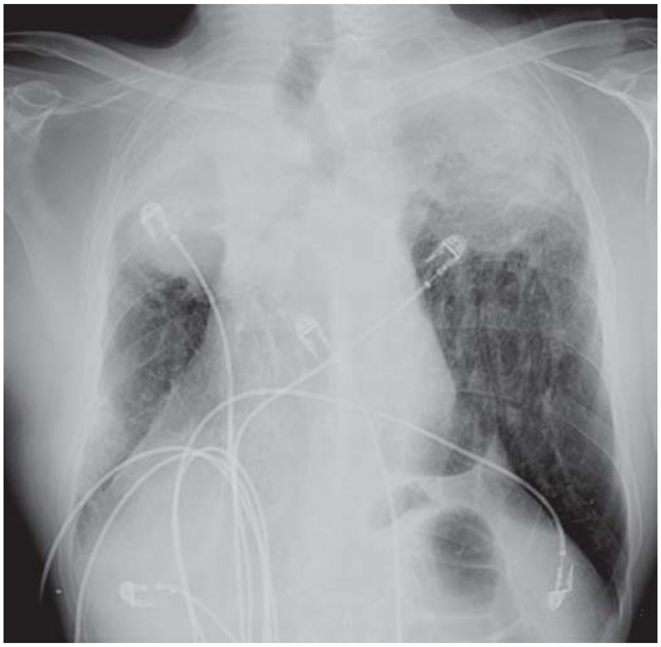

Fig. 106.9: A radiograph shows large opacities in both upper zones with associated calcification and fibrosis consistent with the diagnosis of PMF

Coal dust is much less fibrogenic than silica. As an example, a mixture of 10% silica and 90% coal is far more cytotoxic to macrophages than pure coal dust.[46] However, both dusts, when cleaved, show surface radicals by electron spin resonance spectroscopy. The free radicals generated by crushing anthracite coal are more numerous than those generated from crushing bituminous coal leading to speculation regarding free radical release from different coal ranks and the suggestion that exposure to anthracite coal increases the risk for the development and progression of disease.[47]

Long-term coal dust exposure in animals increases the number of alveolar cells recovered by lavage.[48] In addition, an elevation in the number of blood monocytes and an increased rate of mitosis has been recognized in cells from animals undergoing chronic coal dust inhalation.[49] This suggests that there was recruitment of cells into the lung from the alveolar capillaries and the interstitium of the lung. Recruited "young" AMs appear to be more active in phagocytosis than older AMs. This may imply a more effective clearance of particles.[50]

Exposure of AMs to particles can result in the release of proteolytic enzymes, reactive oxygen species [i.e. hydrogen peroxide (H_2O_2), hydroxyl radical (OH) and superoxide anion (O_2^-)], and leukotrienes via breakdown of arachidonic acid in the cell membrane. Again, silica is a much stronger stimulus to the release of these agents than coal dust.[51] Excessive release of these reactive oxygen species has the potential to overwhelm the naturally protective antioxidant system within the lung and begin the process of inflammation and fibrosis.

Activated macrophages secrete a wide variety of mediators, which can attract neutrophils into the affected area and then stimulate them to release reactive oxygen species and enzymes. Similarly, the macrophage-derived inflammatory factors can act as chemotactic agents for neutrophils (e.g. tumor necrosis factor, interleukin 8 and leukotrienes), and increase neutrophil adherence and reactive enzyme release (platelet-derived growth factor and platelet-activating factor). The presence of these factors escalates the inflammatory process. Finally, secretions of many of the above factors by activated AMs are likely to enhance fibroblast growth and/or stimulate the production of collagen.

Development of Bronchoalveolar Lavage (BAL) as a means for sampling lung cells and fluid has provided an opportunity to study the lung's response to the inhalation of various dusts. Studies of the mechanisms of inflammation and fibrosis using BAL-derived material have opened the possibility for studying at least some of the mechanisms in the pulmonary reactions in CWP.

It has been suggested that constitutional differences may help to explain the variation in response to inhaled dusts, especially the attack rates and progression of CWP. One study looked at the prevalence of histocompatibility antigens in coal miners.[52] So far it has not been possible to confirm any definite association between these factors and CWP.

MANAGEMENT OF CWP

There is no proven therapy for CWP. The primary prevention of lung disease in miners must include continuing efforts at reducing coal mine dust exposure. Management is best directed at prevention, early recognition and treatment of complications. The major challenges to the physician are the recognition and management of airflow obstruction, respiratory infection, hypoxemia, respiratory failure, cor pulmonale, arrhythmias and pneumothorax.

Workers presenting with respiratory symptoms should have careful evaluation. The initial history and examination should be supplemented by chest radiograph, spirometry with bronchodilators, diffusing capacity, electrocardiogram, and resting arterial blood gas measurement as indicated. A thorough initial data base allows accurate assessment of the worker's respiratory health and serves a starting point for observing the response to therapy or progression of disease.

Smoking cessation is important regardless of symptoms of respiratory disease, chest radiograph abnormalities or pulmonary function status. Physician encouragement to stop smoking should be supplemented by support from smoking cessation groups, use of nicotine substitutes and behavior modification techniques.

Symptomatic reversible airflow obstruction should be treated with inhaled bronchodilator therapy as indicated. Patients with severe obstruction and inadequate improvement from the usual measures should be considered for a trial of glucocorticoid therapy.

Hypoxemia can be a serious complication in those with PMF. It is typically present first during exercise, but can occur with rest and during sleep. Chronic hypoxemia can lead to the complications of polycythemia, pulmonary hypertension, cor pulmonale and cerebral dysfunction. Therapy with low-flow oxygen is indicated when the arterial oxygen tension is less than 55 mm Hg or when clinical evidence of cor pulmonale is present.

Miners should receive appropriate immunization with influenza and pneumococcal vaccines. Bacterial and viral episodes of bronchitis or pneumonia should be promptly recognized and appropriately treated. Similarly, miners with concomitant exposure to silica dust (most often roof bolters, drillers and motormen) deserve special attention with regard to mycobacterial infection. Symptoms of weight loss, fever, sweat, change in sputum production or malaise should be promptly investigated with a chest radiograph and examination of the sputum through stain and culture for Acid- Fast Bacillus (AFB). Occasionally the sputum may be negative and the infecting mycobacterial organisms can only be obtained by fiberoptic bronchoscopy with brushings and washings. Active tuberculosis in this population can be usually successfully treated with the usual drug regimens.[53,54] In coal miners with a significant history of concurrent silica exposure, the treatment for tuberculosis may need to be more aggressive, and long-term follow-up is indicated in the view of the reports of recurrent pulmonary tuberculosis in patients with PMF after the completion of apparently adequate therapy.[55]

Pneumothorax can be particularly troublesome in miners with pneumoconiosis. Those with bullous disease in the presence of advanced complicated pneumoconiosis are at the greatest risk. Typically, once the lung collapses, it is difficult to expand, a feature attributable to the decreased compliance associated with interstitial lung disease. Therapy with one or several chest tubes is often therapeutic; however, recurrent pneumothorax that cannot be expanded is recognized and may require an open procedure and pleurodesis.

Respiratory failure may complicate advanced PMF as it does in other chronic respiratory diseases. Ventilatory support measures are indicated when the failure is precipitated by a treatable complication. The application of ventilatory support measures should be discussed with the patient before the need arises. In general, miners with advanced pneumoconiosis are poor candidates for long-term mechanical ventilatory therapy.

Over-all, improved mining methods and lower dust levels appear to be reducing exposures and the new cases of both simple and complicated pneumoconiosis in the

US Medical surveillance programs, using chest radiographs, allow the early recognition of workers with simple pneumoconiosis. Yet, recent work in a series of US coal mines has reminded all that the hazards remain.[56,57] Workers with simple pneumoconiosis should be encouraged to transfer from jobs with high-dust exposure to jobs with low-dust exposure.[58] It is our opinion that any worker with simple CWP should be encouraged to leave dust exposure. Those with category 2 or great pneumoconiosis are at clear risk for progression even in the absence of additional coal dust exposure.

SUMMARY

Coal workers' pneumoconiosis is a disease distinct and separate from silicosis. Although, the coal particle is not nearly as fibrogenic as the silica particle, excessive exposures over a period of time overwhelms effective clearance mechanisms and initiates chronic interstitial lung disease. Simple CWP is clearly related to the amount of dust deposited within the lungs. PMF most often, but not always, occurs on a background of simple CWP and is the result of dust deposition plus other inadequately defined host factors. Immunological and local cellular factors may contribute to the development of this form of the disease.

Progressive massive fibrosis is clearly associated with alterations in the ventilatory, mechanical and vascular function of the lungs. These abnormalities in PMF contribute to the premature morbidity and mortality of this disease. Similarly, there is no therapy for CWP. Prevention remains the cornerstone of eliminating this occupational lung disease. The education of workers and employers regarding the hazards of coal dust exposure and measurement and effective control of dust exposure remains the sole means of eliminating this disease.

Silicosis

PS Shankar, SK Jindal

INTRODUCTION

Exposure to potentially harmful substances may occur at work in certain occupations. Silicosis is the most prevalent chronic occupational lung disease. It is an irreversible and chronic fibrotic disease of the lungs caused by inhalation, retention and pulmonary reaction to large amounts of silica dust, usually in the form of alpha quartz. The condition is an extensively studied occupational disease and it remains among the most serious potentially fatal occupational diseases.[1]

Silica and Silicosis

Silica is a chemical compound, silicon dioxide (SiO_2). Silicon is distributed widely in nature and it contributes to about 28% of the earth's crust. Silicon is highly reactive and does not remain in the state of an element. It combines either with oxygen to form free silica (SiO_2, silicon dioxide) or with oxygen and other cations, such as magnesium, aluminum or iron to form silicates. Examples of silicates include mica, soap-stone, talc, tremolite and cement. Silica and silicates form the bulk of most kinds of rocks, clays and sands. Silica exists in two distinct forms as crystalline and amorphous. "Crystalline" refers to silicon and oxygen atoms oriented and related to each other in a fixed pattern. In amorphous form, silicon and oxygen atoms are distributed in a random fashion.[2]

The term silicosis is applied for the lung disorders caused by inhalation of the free silica. The inhaled silicon dioxide is usually in crystalline form, most often as quartz. Crystalline silica produces different polymorphs at different temperatures and pressure. Alpha quartz (simply referred to as quartz) is stable over most temperatures and pressures found on the earth's surface. It forms the most common polymorph found in the earth's crust. *Cristobalite* and tridymite are other crystalline forms of silica; they are stable at high temperatures and low pressures. Beta quartz is stable at high temperatures.[2] Free silica refers to quartz, cristobalite and tridymite. Since silica is colorless and nonirritant, its exposure in large amounts remains unrecognized. It does not produce any immediate effect in most instances. Chronic exposure leads to a progressive fibrosing disease, which may also predispose to the development of tuberculosis.[3] In high-pressure environment at different temperatures as found in different industrial processes, such as ceramic manufacturing and foundry process, quartz may be heated to high temperatures at high pressures.

The examples of amorphous forms of silica include opal, diatomaceous earth, silica-rich fiberglass, mineral wools and silica glass. Generally they are harmless to humans except the fiberglass.[4]

Occupational Exposure

Silicosis is encountered in mining and quarrying of hard rock, anthracite coal and metals. The sand stone industry, sand blasting, stone quarrying and dressing, granite industry, grinding of metals, sand blasting, iron and steel foundries, brick yards, silica milling, flint crushing, glass making, ceramic manufacturing and manufacturing abrasive soaps are some of the occupations related to silica exposure. There is exposure to silica particles of respirable size with an aerodynamic diameter of 0.5 to

5 microns. In India it has been observed that there is a high risk of silicosis in slate pencil and agate grinding industry.[5,6]

About three million workers who are at high potential risk of silica exposure, are employed in occupations, such as mining and quarries; manufacture of nonmetallic products, such as refractory products, structural clay, glass mica; and manufacture of basic metals and alloys, such as iron and steel, copper, ferro-alloys, aluminum, etc.[7] The development and progression of silicosis frequently occurs after exposure to silica has stopped.

Problem of Silicosis in India

There are several populations in India at high risk of developing silicosis. The workers in gold, mica and coal mines, and those employed in ceramic and pottery industry, agate and slate pencil industry, brick workers and stone cutters are particularly at risk.[8]

Silica sand is an inexpensive and useful component of a variety of manufacturing processes. Rock cutting and rock carving to build temples, sculpturing stone containing granite, mining and metallurgy have been in existence in India since a very long period of time. However, the cases of silicosis were first described by Caplan and Burden only in 1940s in the underground workers of the Kolar Gold fields, Karnataka (then Mysore State).[9] The condition was benign since the free silica dust in Kolar Gold fields did not possess fibrogenic property.[10] Several reports on the occurrence of silicosis became available thereafter.[11-15] Radiographic evidence of silicosis was reported in 28 of 42 stonecutters and 3 of 24 stone breakers.[16] Reports of silicosis in industrial workers soon followed.[17,18]

The epidemiologic studies carried out in India have shown marked variation in the prevalence of silicosis.[5,6,9,14-27] The prevalence rate has varied from 3.5% in ordnance factories to 54.6% in the slate pencil industry. The variation is due to the fact of variability of concentration of silica in work environment of different occupations, duration of exposure and the physical properties of the silica (Table 107.1).

The Indian National Institute of Occupational Health (NIOH) has undertaken environmental and medical surveys in several industries and found the prevalence of silicosis to be very high in most instances.[28] The prevalence of silicosis was attributed to a high concentration of total and respirable dust and the great percentage of free silica in the dust, the free silica levels of between 55% to 60% of total dust were reported at some of the industrial sites; up to half of the workers were reported to suffer from silicosis.[28] The average duration of exposure before the development of silicosis, in most of these surveys, was approximately 10 to 12 years or less. The human cost was great, with approximately 55% of slate pencil industry workers having silicosis nearly 18% developing progressive massive fibrosis and 22% dying within 16 months of diagnosis.[29]

TABLE 107.1: Prevalence of silicosis in India

Industry (ref. no)	*Prevalence (%)*
Iron and steel workers[14]	2.5
Ordnance factory[15]	3.5
Mica mines and mica processing[16]	5.2
Glass bangle workers[17]	7.3
Gold mines[9]	8.8
Emery polishers[18]	0.7
Quartz crushing[19]	12.0
Quartz mill stone grinding	14.0
Ceramic and potteries[20]	15.1
Brick makers[21]	16.7
Stone cutters[22]	20.0
Stone grinding[23]	27.8
Lead and zinc mines[23]	30.4
Mica miners[25]	34.1
Stone cutters[26]	35.2
Agate workers[6]	38.0
Slate pencil workers[5]	54.6

Environmental Pneumoconiosis: An interesting form of nonoccupational pneumoconiosis is reported in some parts of India, mostly from the high altitude villages in Central Ladakh and Kaza in the Himalayas. Silicosis was common in the older inhabitants of villages exposed to frequent dust storms containing free silica.[30] Silica exposure was unrelated to any specific occupation. This condition appears to be similar to that described in residents of the Sahara and the sub-Saharan desert. [31]

Other Asian Countries (Table 107.2)

There are occasional published reports of silicosis from developing countries in Asia (e.g. Nepal, Pakistan, Bangladesh and Sri Lanka) where the environmental and working conditions in factories are similar to those found in India.[32] The problem of silicosis in China and Hong Kong, which accounts for an important health concern, has been extensively investigated.[33-37] The problem remains significant in Japan among workers involved in occupations, such as ceramic industry, tunnel construction and whetstone cutting.[38-40] Silicosis is now recognized more frequently in industrial workforce in

TABLE 107.2: Occurrence of silicosis in different populations at risk from Asian countries

	Population	*No. studied*	*Silicosis (%)*
1. Thailand			
• Yingratanasuk[42]	Stone carvers	97	2
• Aungkasuvapala[41]	Workers in Factories	33	9
2. Vietnam			
• Chien[46]	Brick refractory	158	10
3. China			
• Hong Kong (Law)[35]	Pneumoconiosis outpatient clinic	1056	61.4
• Guangizhou (Jiang)[36]	Agate Mill	32	46.9
• China (Chen et al)[37]	Tin miners	3010	33.7

South Eastern countries, such as Thailand, Singapore and Vietnam.[41-46] A survey among workers in 33 factories in Thailand revealed radiologic silicosis in 61 (9%) workers, while 13 (1.9%) workers had pulmonary tuberculosis.[41] Thirty-one of the thirty-three factories had measurements of either total dust or respirable dust exceeding the threshold limit values. The prevalence of silicosis was 10% in Vietnam among refractory brick workers.[46] This was almost linearly related to the duration of work.[45]

Pathogenesis

Crystalline silica particles are inhaled while the respirable-sized particles are deposited in the distal airways and alveoli. Alveolar macrophages ingest the silica particles, migrate into the interstitium, enter the lymphatics and are transported to the regional lymph nodes.

The interaction of silica and the pulmonary alveolar macrophages is a crucial event in the development of silicosis. Macrophage injury or death will release intercellular proteolytic enzymes that are likely to take part in the lung injury. There is also the release of cytokines, which attract other inflammatory cells such as neutrophils and T-lymphocytes.[47] The injured macrophages and the other inflammatory cells release superoxide anions and hydroxyl radicals and they cause injury to the lung tissue.[48] Silica-activated macrophages and lymphocytes also release many inflammatory mediators, such as interleukin-1 and tumor-necrosis factor that contribute to the production of fibrosis. Silica has great fibrogenic potential and the dying macrophages liberate fibroblast stimulating factor, which causes excessive production and release of collagen by fibroblasts.

Forms of Silicosis

Silicosis has a long latency period and three different patterns of silicosis have been recognized, i.e. chronic, accelerated or acute forms primarily based on the degree and duration of exposure and onset of symptoms.[2] The presentations of the disease reflect the variable intensity of exposure, rate of silica deposition in the lungs, retention of total amount of crystalline silica, latency periods and natural histories.[49]

1. *Chronic (or Classic) Silicosis*: The physiology of chronic silicosis involves chronic inflammation due to the accumulation of a variety of inflammatory mediators and fibrogenic elements. The rate of progression of the disease depends upon the rate and amount of silica deposition and retention in the lungs. The condition can be simple or complicated.

   The simple chronic silicosis develops following exposure to low-to-moderate concentration of free silica overr 20 years or more. Initially, there is collection of silica-laden macrophages in the loose reticulin fibers in the peribronchial, perivascular, paraseptal and subpleural areas. Later, there is formation of silicotic nodules in which the central area gets organized with a concentric whorl-like arrangement of collagen. The lesions may have variable degrees of calcification. The nodules are seen in the pulmonary parenchyma typically in the upper lobes, and the hilar and peribronchial lymph nodes. A few birefringent silica particles may be demonstrated in the center of silicotic nodules under polarized light. They represent inhaled silicate particles mixed with silicon dioxide. The inflammation continues in the periphery of the nodule, which gets enlarged by including adjacent pulmonary structures. Such a stage is referred to as Progressive Massive Fibrosis (PMF).[50]

These nodules are referred to as histologic tornadoes; with a "quiet" center of hyaline and collagen fibers concentrically arranged around the center.[51] In the periphery, there is a collection of inflammatory cells such as macrophages and lymphocytes. Later it becomes the seat of a fibrotic reaction.

In complicated silicosis, the nodules coalesce to form large masses of hyalinized tissue. The masses may have a variable diameter of 2 cm or more. The blood vessels and bronchioles are obliterated. The amount of silica or inflammatory cells is negligible. They are found in the apices of the lung, and tend to be bilaterally symmetrical in distribution. There can be central necrosis and cavitation. These patients exhibit an increased susceptibility to infection with *Mycobacterium tuberculosis,* as a result of which the lesion may get cavitated.

2. *Accelerated Silicosis*: The condition is encountered in persons who are exposed to heavy amounts of silica, often over a period of 5 to 10 years. Accelerated silicosis occurs over a relatively shorter time course when compared with chronic silicosis. The rate of progression is more rapid. The condition progresses even after removal of the person from the continued silica exposure. Pathologically, there is filling of alveolar spaces with eosinophilic granular material. The collagen vascular diseases, such as systemic sclerosis, systemic lupus erythematosus and rheumatoid arthritis, are sometimes associated with this type of silicosis.
3. *Acute Silicosis:* Acute silicosis is rare, but often fatal. It is likely to occur in workers as a consequence of intense exposure to very high concentrations of silica over a period varying from several months up to about five years. Cases have been encountered in sandblasters, in silica flour manufacturing and rock drilling. The mechanism of injury is different from that seen in chronic silicosis. There is a stronger inflammatory response due to the presence of freshly fractured silica exhibiting abundant cleaved particle surfaces. Lungs exhibit consolidation without silicotic nodules. The lungs involved by acute silicosis show presence of hypertrophic type II pneumonocytes lining the alveoli. They are responsible for the production of an excess amount of proteinaceous material and surfactant protein. The alveolar spaces are filled with eosinophilic proteinaceous material. This is referred to as silicoproteinosis. There is diffuse alveolar damage and desquamative pneumonitis.

Clinical Features

The most common presentation of silicosis is in the form of uncomplicated chronic silicosis. Chronic silicosis develops only after decades of repeated exposures to high concentrations of silica dust. Generally, it is asymptomatic even when the radiographic appearance suggests fairly advanced silicosis. Dyspnea on exertion is considered to be the most frequent and directly related symptom of silicosis.[1] There can be cough and sputum production from nonspecific bronchitis or from cigarette smoking. Chest pain and hemoptysis indicate the likely complication of tuberculosis. Acute silicosis presents with dyspnea, fatigue, weight loss, fever and pleuritic pain. Rarely, bilateral pneumothorax is also reported.[52]

In addition to the development of pneumoconiosis in silica-exposed workers, there are several reports on increased respiratory symptoms and impaired lung function in industrial workers, miners, stone cutters and others in the absence of a definitive radiological diagnosis of silicosis.[53-55] This nonspecific symptomatology is attributed to chronic dust exposure. Stunting of lung growth is reported on long term exposure to respirable dust in childhood and early adult life.[53]

Diagnosis

Clinical and radiological features that distinguish silicosis from other fibrotic disease include the following:

i. Occupational exposure to a substantial amount of silica,
ii. Silicotic nodule, and/or
iii. Involvement of hilar lymph nodes.

Radiologically, there is a close resemblance between silicosis and miliary tuberculosis. However the size of nodules seen in tuberculosis, are less than those seen in silicosis. The radiographs of patients with silicosis usually exhibit an increased translucency as against general loss of translucency in tuberculosis.[1]

The symptoms in a patient with simple nodular silicosis are markedly less in comparison to the patients with miliary tuberculosis. Furthermore, the incidence of miliary tuberculosis in adults is less common and exhibits toxic manifestations. The distinction between PMF and post-primary tuberculosis may pose difficulties sometimes. The conglomerate shadows of PMF do not show cavitation. The PMF often exhibits large fibrotic masses with an upward displacement of the mediastinal and hilar structures from volume loss. The lower lung zones may remain hyperinflated and emphysematous. The onset of cavitation should prompt a search for an active mycobacterial disease. Associated features, such as

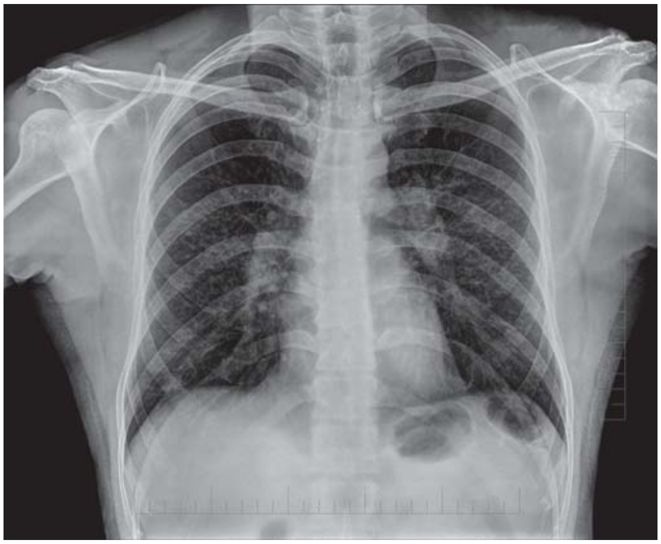

Fig. 107.1: Chest radiograph of a patient of silicosis demonstrating hilar lymphadenopathy and small nodular infiltrates

pleural effusion, localized increase in size of opacities and distortion of intrathoracic structures due to fibrosis are noted in tuberculosis.

Acute silicosis produces a homogeneous ground glass appearance on chest radiograph. It has to be distinguished from pulmonary edema, alveolar hemorrhage, pulmonary alveolar proteinosis, pneumonia and bronchoalveolar cell carcinoma.

Radiographic Patterns

The diagnosis of silicosis is established by a history of occupational exposure, and chest radiograph with typical nodules. Exclusion of other diseases and very rarely, histologic examination of lung tissues may be necessary.

Chest radiography is vital for the diagnosis of silicosis (Fig. 107.1). There is a clear relationship between total dust exposure and severity of radiographic changes. In the initial stages, there is reticulation of the lung fields due to thickening of the perivascular and intercommunicating lymphatics. The diagnosis of silicosis is possible only after the appearance of nodules.

The classic radiographic features of simple silicosis are rounded opacities ranging in size from 1 to 10 mm and occurring predominantly in the upper lung zones. They can be categorized using the International Labour Organization (ILO) International classification of radiographs of pneumoconiosis on the basis of size, shape and profusion category.[56]

The small rounded opacities are grouped into three diameter ranges designated as "p" (up to 1.5 mm), "q" (1.5 to 3.0 mm) and "y" (1.0 to 10 mm). As the disease progresses, the opacities are also seen in the mid- and lower-lung zones. The nodules are of homogeneous density and usually bilaterally symmetrical.

In addition to the size and shape of the nodules, the abundance (profusion of nodules within the parenchyma) of the lung is also important. By comparison with standard films provided by the ILO, the profusion of nodules in the patient's films can be categorized in order of increasing severity as category 1, category 2 or category 3.

Hilar lymphadenopathy is also seen sometimes in advanced nodular parenchymal shadows. There can be "egg shell" calcification of the lymph nodes, and it is strongly suggestive of silicosis. However the egg shell calcification is not specific and it may be seen with sarcoidosis, radiation-treated Hodgkin's disease, blastomycosis, scleroderma, amyloidosis or histoplasmosis.[57]

On continued dust exposure, the nodule increase in size and number ultimately covering most parts of the lungs. They may unite and form conglomerate shadows, which are described as PMF. The ILO classifies these large opacities as A, B and C based on size or on total cross sectional area relative to the size of right upper zone (or on both). With coalescence of the nodules, the upper lobes become fibrotic and contract making the conglomerate nodules to migrate towards the hilar areas. The hilar structures are pulled upward, leaving areas of compensatory emphysema at their margins and in the lung bases. With these alterations the small rounded opacities that were evident previously on the radiograph become less visible or may at times disappear. Pleural abnormalities are not commonly encountered, but they may be sometimes seen in the lesions.

Acute silicosis may present with radiographic alveolar filling pattern leading to a ground glass appearance, and association with conglomerate silicotic nodules is rarely seen. Pulmonary tuberculosis in the patient with silicosis may be associated with pleural effusion, localized increase in the size of opacities and cavitation.

Pulmonary Functions

Pulmonary function tests help in the evaluation of persons with suspected silicosis. There are no specific patterns of ventilatory impairment in silicosis. There can be significant airflow limitation. Both Peak Expiratory Flow (PEF) and Forced Vital Capacity (FVC) are reported to reduce in chronically exposed individuals.[53-55] Tobacco smoking in the presence of other dust exposure further aggravates the presence of airway obstruction. In patients with PMF, restrictive ventilatory impairment is seen in association with arterial hypoxemia. The pulmonary function changes occur earlier and are more marked in acute and accelerated silicosis. They make a rapid progress compared to chronic form of the disease.

Other Investigations

Bronchoalveolar Lavage (BAL) study is rarely indicated. It may be undertaken when exposure history and clinical presentations are atypical. The BAL fluid of workers exposed to quartz dust will demonstrate an increased number of cells, protein and quartz in the macrophages. The amount of mineral dust in BAL fluid cells is related to the intensity of exposure and duration of employment.

Lung biopsy (open or thoracoscopic) is rarely needed to establish the diagnosis. It may be indicated in some clinical settings when complications are present. This is particularly important when lung malignancy is suspected as a complication (Fig. 107.1).

The demonstration of tubercle bacilli in the sputum of patients suffering from silicotuberculosis is difficult in many instances. The walling in of the tubercle foci by the silicotic fibrosis prevents the elimination of tubercle bacilli in the sputum.

Complications (Table 107.3)

In the presence of worsening of respiratory symptoms and rapidly changing or progressive lesions on chest radiographs, mycobacterial infection (*Mycobacterium tuberculosis* or atypical mycobacteria) should be suspected and investigated. Tuberculosis can either complicate silicosis or pose a problem in the differential diagnosis. There is an increased susceptibility to pulmonary tuberculosis and rarely to fungal infection. It is thought that macrophage dysfunction caused by the presence of silica appears to be the cause of increased susceptibility to tuberculosis and other infections.

TABLE 107.3: Important complications seen in patients with silicosis

1. Pulmonary hypertension and chronic cor pulmonale
2. Chronic respiratory failure
3. Respiratory infections
4. Silicotuberculosis
5. Silicomycosis
6. Autoimmune disorders
7. Necrotizing nodules–Caplan Syndrome
8. Scar carcinoma
9. Acute/Accelerated silicosis–Alveolar proteinosis
10. Massive pulmonary fibrosis

TABLE 107.4: Characteristics of tuberculosis in silicotics

- Frequent occurrence
- Increased risk
- Severe and persistence respiratory symptoms
- Rapid progression to fibrosis
- Poor response to antituberculosis therapy
- Necessity of longer duration of therapy

Patients with PMF are prone to mycobacterial infections and spontaneous pneumothorax. Tuberculosis has been reported in 18.6% of mica workers and 60% of workers in the pottery and ceramic industries.[26,29] The prevalence of tuberculosis has varied from 1.9% to 3.6% in brick makers, metal workers and coal miners with silicosis. According to NIOH reports, tuberculosis was present in 4.8% of coal miners and 48% of stone cutters.[19] Silicotuberculosis has been identified as an important comorbidity in several other Asian populations.[41,43,58] Even in the developed countries, such as Japan, silica exposure had a significant association with tuberculosis.[45,39]

Reports appearing in the past few decades continue to identify a clinically important rate of tuberculosis in silicotics. Tuberculosis exhibits the same specific characteristics in persons with silicosis (Table 107.4).

Free silica impairs macrophage function, thereby increasing the chances of mycobacterial infection.[59,60] Important predisposing factors relate to social circumstances and to living and working conditions. Tobacco smoking is an important predisposing factor. Most of these workers live in crowded and unsanitary conditions, while their jobs are in dusty environments and silica exposures are not controlled. The chances of spread of infection are higher in such surroundings. Many reports of silicotuberculosis cited earlier do not necessarily attribute the presence of tuberculosis to underlying silicosis. However, when the conditions are present together, there is an increased morbidity and mortality, with clear evidence of rapid silicosis progression. Studies from Singapore have reported the occurrence of tuberculosis as a significant factor associated with the development of progressive massive fibrosis and a strong predictor of mortality in patients with silicosis.[61,62] Occasionally silicosis is complicated by fungal invasion (Fig. 107. 2). Aspergillosis complicating a cavitary silicotic nodule is also reported.[63]

There is an increased incidence of autoimmunity and diseases, such as rheumatoid arthritis in patients with silicosis. These patients exhibit positive latex fixation tests, antinuclear antibodies and increased levels of

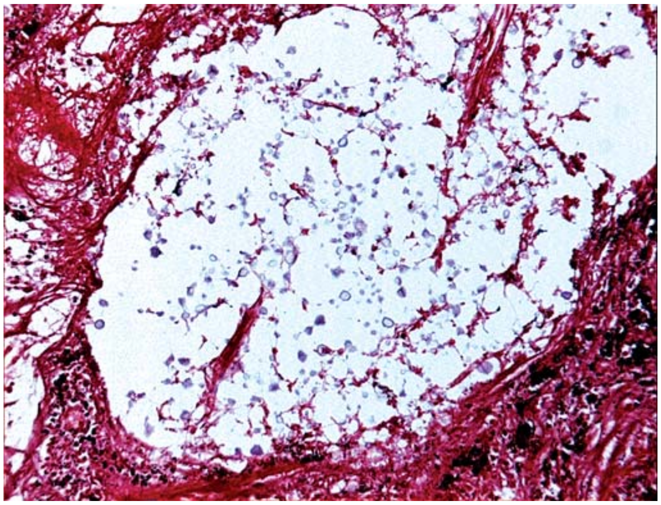

Fig. 107.2: Post-mortem lung histology-Photomicrograph showing silico-mycosis. Clusters of Cryptococci and fibro-collagenous material with extensive blackish pigment, which revealed needle shaped silica particles under polarized light examination (Courtesy: Dr Ashim Das, Department of Pathology, PGIMER, Chandigarh)

immunoglobulins. Necrotizing rheumatoid nodule in silicosis is a characteristic clinical picture, which is known as Caplan Syndrome. Chronic silicosis gradually leads to development of pulmonary hypertension, chronic cor pulmonale and chronic respiratory failure. The onset of these complications is rapid in case of massive fibrosis.

There is an increased relationship between quartz exposure, silicosis and development of bronchogenic carcinoma. Furthermore, there is an increased mortality from lung cancer among workers exposed to silica dust.[64-66] This cancer is mostly an adenocarcinoma, which commonly occurs over a silicotic scar in the lung (Fig. 107.3). Tobacco smoking acts as an added risk factor for carcinogenesis.

Prognosis

Patients with conglomerate fibrosis progress to cor pulmonale and respiratory failure. The clinical course of patients with acute silicosis is inexorably downwards with the development of pulmonary fibrosis, followed by restrictive lung disease and ultimately respiratory failure resulting in death. Silicosis especially when "acute" may be complicated by secondary alveolar proteinosis with marked respiratory distress and failure.

Treatment

There is no specific treatment for silicosis and the therapy is directed largely at the complications of the disease. Corticosteroids and aluminum citrate have been used with varying success in silicosis.[67-69] Corticosteroids have limited efficacy in the treatment of silicosis.[68,69] Inhaled aluminum citrate powder coats silica particles retained within the lung, thereby reducing the solubility of those particles. It has been proved to be unsuccessful.[21] The polymers such as Polyvinyl Pyridine N-Oxide (PVPNO) and polybetaine though showed protective effects in experimental animals, were not found suitable for human disease. Tetrandrine though found to diminish fibrosis and collagen synthesis in silica-exposed animals has not found to be effective in humans and has shown to be teratogenic.

Following the diagnosis of silicosis, it is advisable to avoid further exposure to silica-containing dusts. The individual should be promptly removed from such surroundings. In advanced disease or if it has developed following a short exposure, further exposure to dust has to be avoided. The comorbid conditions, such as chronic obstructive pulmonary disease should be identified and managed.[70-72] Severe airflow obstruction and cor pulmonale are treated with bronchodilators, diuretics and oxygen. Tobacco smoking, if present must be stopped.

Treatment of tuberculosis in these workers poses tremendous problems. Results of standard chemotherapeutic protocols for tuberculosis in the presence of silicosis are less effective than therapy for tuberculosis alone.[73] A partial explanation for the poor response has been attributed to impaired macrophage function and poor penetration of the drugs into the fibrotic nodules.[58-60] Short course chemotherapy with two months of streptomycin, isoniazid, rifampicin and pyrazinamide followed by seven months of daily isoniazid and rifampicin was effective, with only a 5% failure rate in 16 previously treated silicotics and 56 anthrasilicotic patients with mycobacterial positivity.[73] Clinical comparison was made between two antituberculosis treatment regimens, comprising of four primary drugs administered thrice weekly for six and eight months in 240 Chinese silicotics. Although the six-month regimen was inadequate, since 22% of 41 patients relapsed bacteriologically during the first 3 years, the 8-month regimen was substantially found to be more effective.[73]

It is generally recommended that patients with tuberculosis should receive at least four antimycobacterial drugs, such as isoniazid, rifampicin and pyrazinamide for two months followed by two antituberculosis drugs (isoniazid and rifampicin) for a total of nine months or longer. The exact duration of therapy remains debatable.

Acute silicosis with respiratory failure needs aggressive treatment that includes whole-lung lavage in an attempt to improve gas exchange and to remove alveolar debris. However the benefit has yet not been established.[74] Though a short-term controlled trial of systemic corticosteroids improved lung function in patients with silicosis, majority of studies have not shown any benefit.

Prevention

Prevention remains the main goal of silicosis. It comprises of medical screening and surveillance and dust control measures.

Medical Surveillance: Workers exposed to silica dust should undergo periodic medical examination to screen for adverse health effects and dust measurements in work environment.[75] The medical examination comprises of preemployment and periodic examinations including chest radiographs, sputum examination for tubercle bacilli and spirometry. The preemployment medical examination provides the base-line data for each individual. The periodic medical examination helps in early detection of silicosis and silicotuberculosis. Health education is important to get active cooperation of the workers at risk.

Dust Control Measures: Silicosis does not develop without exposure to dust. The dust levels in the work place correlate well with the incidence and severity of the disease. Hence elimination or suppression of dust at the work place forms the essence in the control of silicosis. The work process should be isolated and enclosed. Adequate ventilation should be provided. Personal protection is important.

Exposure to dust can be reduced by the use of improved ventilation and local exhaust, use of substitution innocuous substances that are less hazardous than silica, isolation and enclosure of the sources of dust, use of wet abrasive techniques, humidification of work environment and personal protection. Masks are advocated only when other dust control measures have failed. The dust masks are of little value when the dust concentrations are high as the dust particles will clog the pores in the filter.[1] Further, masks are less suited for hot and humid climate.

In summary, silicosis is an old disease, which remains a major occupational health hazard in India and is responsible for high, morbidity and mortality in industrial workers. Workers exposed to high concentrations of free crystalline silica in unprotected settings are at great risk for developing pulmonary fibrosis. The disease is progressive and irreversible. All measures should be undertaken to avoid and control dust exposure. The lack of therapy emphasizes the importance of primary prevention in our approach to the problem.

Berylliosis

PS Shankar

INTRODUCTION

Beryllium (Be), a light metal exhibiting thermal and electrical conductivity and tensile strength, is found in the Earth's crust. Beryllium-containing minerals are processed to beryllium metal, beryllium alloys and beryllium oxide for use in the aircraft industry, nuclear reactors, electronics industries and manufacture of heat-resistant ceramics and fluorescent lamp industries. Mining, industrial processing, smelting and fabrication of beryllium or its alloys result in the emission of beryllium to the atmosphere, surface waters and soil.[1] There is little recognition of berylliosis in India, but for an occasional report.[2] Beryllium exposure is associated with both acute and chronic manifestations.[3,4] The recent evidence in fact suggests that both the acute and the chronic forms of berylliosis represent a continuum of disease involving hypersensitivity.[5]

Acute Beryllium Disease

Beryllium enters the lungs by inhalation route. Massive exposure induces a generalized acute inflammatory reaction in the respiratory tract and alveoli resulting in tracheobronchitis and chemical pneumonitis [Acute Beryllium Disease (ABD)]. It appears to be due to an irritative phenomenon from direct toxicity.[3] Improved industrial hygiene standards have reduced its incidence.

Chronic Beryllium Disease

Exposure to low concentrations of beryllium over a long period of time may cause a chronic form of disease [Chronic Beryllium Disease (CBD), berylliosis]. The condition has a delayed onset with granulomatous response and pursues a chronic course. Long-term exposure is responsible for a mixed pattern of lung function impairment, pulmonary fibrosis, cavitary lung lesions, pneumothorax and respiratory infections.[4,6]

Ingested beryllium is poorly absorbed from the gastrointestinal tract. It gets accumulated in the skeleton and gets eliminated very slowly through the kidney.[7] Beryllium is a potent chemical sensitizer. Direct contact of soluble beryllium compounds with skin or mucosa causes allergic contact dermatitis and ulcers in susceptible persons. Occupational exposure to beryllium can also result in an increased incidence of lung cancer.[8]

PATHOGENESIS

Chronic beryllium disease is primarily an inflammatory lung disease due to an inhalational exposure to both soluble and insoluble forms of beryllium. Beryllium is one of the most toxic elements. It occurs as an industrial hazard. Unusually, it can also develop in nonindustrial workers who reside near beryllium-plants exposing themselves to airborne emission from the plant. It is characterized by the formation of granulomas with varying degree of interstitial fibrosis, due to a delayed cell-mediated immune response to beryllium particles in the lung.[9] It may develop in a fraction of exposed workers (1.5%) especially those who are genetically predisposed.[10] Alleles of the major histocompatibility gene, Human Leukocyte Antigen-DP (HLA-DP) are associated with genetic susceptibility to CBD.[4,11]

CBD is caused only by inhalation of beryllium in a low dosage over a long period of time (10 or more years).[11,12] Inhaled beryllium gets deposited in the periphery of the lung. The minute beryllium ion functions like a haptene that binds with normal lung protein to form an antigen. This antigen is presented to helper T-cells, which form sensitized T-cells. These cells proliferate in response to beryllium in a dose-dependent manner. There is an increased secretion of lymphokines leading to formation of clusters of macrophages. It produces non-caseating granulomas in the pulmonary interstitium along with diffuse interstitial inflammation and fibrosis. Hilar lymphadenopathy may be present. Thus the condition will have many of the characteristics of sarcoidosis. Unlike sarcoidosis, the antigen is known in CBD.

CLINICAL AND RADIOLOGICAL FEATURES

Berylliosis can present as an allergic immune response (beryllium sensitization, acute toxic pneumonitis – like reaction, or CBD)[11] (Table 108. 1). The manifestations of chronic berylliosis develop very gradually with progressively increasing dyspnea, weakness, fatigue, loss of weight, arthralgia and cough with mucoid sputum. On physical examination, there may be evidence of clubbing and bibasilar crackles at lung bases. Systemic examination may show skin rashes, hepatomegaly and lymphadenopathy. Radiogram of the chest shows diffuse round and reticular nodules, which later progress to diffuse linear fibrosis throughout the lung fields or remain confined to the upper lobes.[13] The hilar nodes are enlarged. It must be noted that hilar adenopathy does not occur in the absence of lung changes. High Resolution Computed Tomography (HRCT) findings significantly improve the diagnostic accuracy.[14] In both stages there is development of extensive interstitial pulmonary fibrosis and pulmonary hypertension. Both the clinical and the radiological picture at this stage may show features of chronic cor pulmonale and cardiac and respiratory failure.

TABLE 108.1: Clinical features of different types of beryllium exposure

Type of Berylliosis	*Clinical Features*
1. Beryllium hypersensitivity	– Usually asymptomatic–sometimes skin rashes, nasal and constitutional symptoms – Positive beryllium lymphocyte transformation test – Progression to berylliosis
2. Acute beryllium disease	– Irritative, chemical phenomenon – Acute tracheobronchitis – Chemical pneumonitis
3. Chronic beryllium disease (Berylliosis)	– Develops gradually over years – Progressively increasing dyspnea, cough, weakness, fatigue, and weight loss – Systemic manifestations – Pulmonary fibrosis, chronic cor pulmonale

DIAGNOSIS

Diagnosis is generally suspected on the basis of history of exposure, clinical manifestations and radiography. Pulmonary functions show a restrictive pattern and reduction in the diffusion capacity. Occasionally there is hyperuricemia and hypercalcemia. On bronchoscopic examination, there is an increase in number of CD4+T cells in BAL fluid.[15] Presence of non-caseating granuloma on transbronchial lung biopsy specimens greatly support the diagnosis. Blood or BAL lymphocyte transformation test is generally positive.[15] Patients with chronic berylliosis exhibit cutaneous delayed hypersensitivity to a patch test with 1% to 2% beryllium nitrate or sulfate. As there is a danger of flaring-up of the underlying lung lesions following the test, it is not widely used.

A blood test to detect beryllium-specific cell proliferative responses in the blood of beryllium-exposed workers referred to as Beryllium Lymphocyte Proliferation Test (BelPT) is used as a biomarker of beryllium-health effect. It consists of in vitro culture of lymphocytes obtained from peripheral blood and then exposure to soluble beryllium sulfate to stimulate lymphocyte proliferation.[16] Occurrence of beryllium-specific proliferation implies Beryllium Sensitization (BeS). The test is being increasingly used in workplace screening and surveillance efforts to detect beryllium sensitization and CBD. Those exhibiting abnormal blood BelPT results require clinical evaluation with bronchoalveolar lavage and transbronchial lung biopsy to confirm diagnosis of CBD. The response is more prominent in the lung cells in comparison to the blood cells.

Beryllium sensitization precedes CBD. However, the natural history and rate of progression from sensitization to disease are not completely understood. In a longitudinal cohort study of a group of individuals detected as having BeS without any evidence of CBD, 31% individuals progressed to CBD over a period of 3.8 years, as evidenced by granulomatosis and/ or mononuclear cell infiltrates in the lung tissue.[17]

TREATMENT

The most important step in the management involves the cessation of beryllium exposure. This is not only important for symptomatic treatment of beryllium hypersensitivity and acute toxicity, but also for prevention of CBD.[18] Corticosteroids constitute the mainstay of treatment for CBD.[19,20] Presently no randomized trials are available to assess the therapeutic efficacy of corticosteroids. However, long term steroid therapy is helpful in suppressing granulomatous lesions and in stopping the evolution of fibrosis.[19] Treatment is generally monitored by using pulmonary function tests and HRCT of the chest.[20] The treatment is of little help after the development of pulmonary fibrosis, but does help in the management of cardiac and respiratory failure.

In experimental studies, some chelating agents have been shown to reduce beryllium concentration in the liver, kidney and lungs of rats.[21] Their clinical use is not yet known. Diminution in the ambient levels of beryllium shows an improvement in the pulmonary status of the workers.

Hard Metal Lung Diseases

Dilip Maydeo, Nikhil Sarangdhar

INTRODUCTION

There are a number of metals that are associated with the development of a variety of lung diseases such as diffuse parenchymal lung disease. The list of such metals continues to expand, and includes aluminum, cadmium, cobalt, copper, iron and others. They can induce a wide range of abnormalities, including lung fibrosis, reactive airway disease, chemical pneumonitis, granulomatous interstitial pneumonitis and cancer.[1,2] Metal fume fever is an acute, short-lived response mediated by the release of specific cytokines, typically in response to zinc oxides. Airway diseases, such as asthma occur in response to the inhalation of antigenic metals such as chromium, nickel or cobalt. Hard metal is generally produced by compacting powdered tungsten carbide (WC), cobalt (Co), and some other agents into a polycrystalline material, a process known as sintering, hence the term "sintered carbides" (or cemented carbides) is also sometimes used.

Incidence

The incidence of granulomatous lung disease in workers exposed to the hard metals is unknown. Only rare case reports have described the disease in affected workers. Although the problem is well recognized in clinical practice in India, the published literature is rather scarce.[3, 4] Due to the relative paucity of reports on these other metals, disease incidence can be inferred to be low. Several factors may contribute to the lower rates, such as the lower exposure to the respirable and ultrafine particulates, particle deposition and clearance in the upper airway that protect the lower airways from exposure.[5]

ETIOLOGY AND PATHOGENESIS

Metals that cause parenchymal lung disease do so by inducing formation of granulomas in the lung. Varying degrees of fibrosis are found with aluminum, cobalt, copper and rare earth exposure. Histologically, the pathologic lesion is composed of a cluster of immune effector cells, predominantly lymphocytes, macrophages, epithelioid cells, multinucleated giant cells, mast cells and fibroblasts.[6] Different metals may induce different types of immune responses (Table 109.1). Unlike in berylliosis, the recognition of both immunopathogenesis and genetic susceptibility are inadequate.[1,2]

Whereas typical protein and polysaccharide antigens are processed and degraded following antigen presentation, metals are unique in that the antigenic metal is frequently retained in the lung and may be detected in the center of the surrounding granuloma. It is possible that retention of the antigen contributes to the formation of a non-caseating granuloma, as well as to the eventual progression to fibrosis.[7] Other metals can trigger a

TABLE 109.1: Types of immune response in metal induced lung disease

2. **Giant-cell granuloma:** Hard Metal (Tungsten carbide and Cobalt)
3. **Foreign-body type reaction:** Copper and Barium

specific immune response. Aluminum, cobalt, gold and zirconium stimulate a delayed-type hypersensitivity response following intradermal injection, analogous to the purified protein derivative, in certain susceptible individuals. Aluminum, cobalt, gold and titanium can also trigger in vitro lymphocyte proliferation.

However, the pathology of Hard Metal Lung Disease (HMLD) is unique in that it is characterized by the presence of "cannibalistic" multinucleated giant cells in air spaces and bronchoalveolar lavage fluid.[8]

CLINICAL FEATURES

Acute pneumonitis is seen in response to high-dose exposures (e.g. copper sulfate solution). Disease symptoms typically begin with the subtle onset of dyspnea on exertion, nonproductive cough, fatigue, low-grade fever and weight loss. In the case of cobalt and copper-associated disease, systemic symptoms such as fever and night sweats may also occur. Vineyard sprayers may present with cough, shortness of breath, recurrent respiratory infections, fever, purulent sputum or hemoptysis.[9] The chest examination may demonstrate fine or dry rales, or it may be normal.

The clinical presentation of HMLD resembles hypersensitivity pneumonitis, with some patients having episodes of work-related subacute disease and some patients evolving, more or less rapidly, to lung fibrosis. Occasionally hard metal alveolitis is accompanied by other inflammatory disorders such as rheumatoid arthritis.[10] One important aspect of HMLD is that the disease may occur after a short duration of exposure, thus suggesting that individual susceptibility, rather than cumulative exposure, plays a major role.[5]

DIAGNOSIS

A careful occupational and environmental history may implicate the etiologic metal involved. The history should include a listing of jobs that entailed metal dust or fume exposures, metals used, and conditions of exposure (use of respiratory protection, availability of exhaust ventilation). Exposure may also be assessed through measurements of urinary and Exhaled Breath Condensate (EBC) concentrations.[11]

Radiology plays an important role, with the disease being frequently noticed on a routine chest X-ray film. Computerized tomography (CT) of the chest reveals the extent of involvement. The chest radiograph demonstrates different patterns of irregular or reticulonodular infiltrates in response to different metals (Table 109. 2).

TABLE 109.2: Chest radiologic abnormalities in different hard-metal diseases

Metal	*Chest Radiologic abnormalities*
Aluminum	Reticular infiltrates, usually bilateral with predominant upper zone involvement
Barium	Small, round or reticular opacities
Cobalt	Round nodular infiltrates; Irregular opacities
Copper	nodular or fine military shadows initially, later progressive fibroids
Gold	Reticular/ reticulonodular interstitial fibrosis
Titanium	Reticular/ reticulo-nodular or nodular infiltrates
Zirconium	Bilateral irregular opacities

High resolution computed tomography may demonstrate increased reticulation, patchy ground-glass opacities, traction bronchiectasis, consolidation and large peripheral cystic spaces, typically distributed in upper and mid lung zones.[12,13]

Patients with suspected disease should undergo pulmonary function tests. These typically show airflow obstruction early in the disease process, with subsequent mixed patterns of obstruction and restriction, and pure restriction in advanced or end-stage disease. Smoking is an important contributory factor to the decline in FEV_1 over time.[14] Hypoxemia can occur with advanced fibrosis in parenchymal disease associated with copper, and rare earth (lanthanide) metals. Pulmonary function tests and blood gases may also be normal, as in the few reported cases of zirconium-associated lung disease.

The definitive diagnosis of granulomatous lung disease is established by lung biopsy. The range of histopathological findings varies from focal peribronchiolar inflammation to diffuse interstitial fibrosis and honeycombing.[15] The real challenge is to link pathology to the exposure of the metal. Typical histological findings include poorly formed non-caseating granulomas infrequently indistinguishable from those found in sarcoidosis or giant-cells in HMLD.[16] Other histologic features include an interstitial mononuclear cell infiltrate, multinucleated giant cells, T-lymphocytes, and varying degrees of fibrosis.

Detection of metal in the bronchoalveolar-lavage fluid, in the granuloma, or by lung tissue particle analysis helps to establish the association of disease with metal exposure, but does not necessarily prove causation. It may be possible to demonstrate a specific immune reaction to the metal by patch testing, as in aluminum, cobalt, gold, or zirconium exposure. *In vitro* lymphocyte proliferation tests to the metal in question, as has been demonstrated with aluminum, cobalt, gold and titanium might help in establishing the presence of a specific immune response.

Occurrence of as well as increased mortality from lung cancer due to chronic hard metal exposure is well established.[17,18] Diagnosis of lung cancer in an exposed individual whenever suspected on the basis of clinical and roentgenological criteria should be confirmed by histopathological examination.

TREATMENT

Primary prevention is the best treatment, given our limited ability to halt or reverse the progression of disease once the patient has progressed to end-stage fibrosis and persistent granulomatous inflammation. The best hope for prevention is to substitute safer working materials, limit the number of exposed workers, and implement tight industrial hygiene controls. Smoking cessation also constitutes an important component of management.

There is limited data suggesting that reducing future exposure to metals can positively affect the course of illness, but doing so is nonetheless considered medically prudent. Medical treatment is indicated in symptomatic patients, and is largely aimed at reducing lung inflammation and palliating the secondary consequences of hypoxemia, pulmonary hypertension, and right heart failure. Corticosteroids are helpful for providing symptomatic relief from acute alveolitis and metal fume fever. Cytokine therapy, such as antitumor necrosis factor-α -receptor blockers may be helpful in the future to inactivate those mediators that participate in the development of fibrosis. Supplemental oxygen, limited use of diuretics, calcium-channel blockers, and angiotensin-converting enzyme inhibitors are well-used second-line therapy for pulmonary hypertension and right-sided heart failure. Pulmonary rehabilitation helps patients to carry out their activities despite of impairment.

The Health Risks of Asbestos Exposure Inhalation

Daniel E Banks, Harakh V Dedhia

INTRODUCTION

The term “asbestos” describes six different occurring fibrous crystals (crocidolite, amosite, chrysotile, anthophyllite, tremolite and actinolite) with a great number of industrial uses. An association between environmental or occupational exposure to asbestos and the occurrence of chest disease is well established in Table 110.1.

The relationship of asbestos exposure to alterations in the pleura, mesothelioma, lung cancer and asbestosis has been clarified in the past decades. Although the case in nearly all instances, direct occupational exposure is not necessary for disease. Unrecognized asbestos exposure may be indirect, occurring in the construction industry, the shipyards or in asbestos workers’ homes. Of particular importance is the latency period between exposure and clinically-detectable disease, typically approximating or exceeding 20 years. When these illnesses are under consideration, a detailed occupational and family history is necessary to recognize the role of asbestos exposure in disease.

During the second half of the last century, regulatory bodies of the world’s developed countries recognized the risks associated with the inhalation of asbestos fibers and acted on this information. Using asbestosis, and to a lesser degree, lung cancer and mesothelioma, as markers for exposures, these adverse health effects have dramatically declined in populations at risk. Yet, this has occurred despite an increase in life expectancy. For example, in 1950, 40 year old white men in the United States were projected to live 31.2 more years. In 2001, this same population had a projected survival of 37.3 years. Non-white men in this age group had a projected survival of 27.3 and 32.5 years at these points in time, respectively.[1] With this increase in life expectancy comes a potential increase in latency period. With this increase in longevity, it is reasonable to expect that workers with asbestos exposure would have a longer time to first, develop disease, and second, progress to more severe disease. Additionally, the population of workers at risk for mesothelioma would have a longer time period to develop this illness and this illness would likely occur more frequently. Similarly, those with asbestos exposure who smoke cigarettes would have a prolonged time to develop lung cancer, even after they stopped smoking. With these insights, if asbestos exposures had remained the same, these additional years of survival would have resulted in more frequent and more severe dust-induced chest illnesses.

TABLE 110.1: Asbestos-related pulmonary effects

1. Asbestosis (asbestos pneumoconiosis)
2. Pleural plaques
3. Pleural effusion (benign)
4. Diffuse pleural thickening
4. Pleural mesothelioma
5. Lung cancer

Yet, the picture that has developed is dramatically different. This is due to a substantial decrease (typically of several orders of magnitude) in respirable exposures. These lesser exposures are reflected in longer survival. Although there are no reports which clearly identify the prevalence of asbestos related illnesses which are truly “representative” of a generation of workers, we have taken the liberty to quote several studies which may be considered "representative" of the decade(s) that the workers were employed and the year of publication. Selikoff, in 1965, reported on a population of asbestos workers with a 40 year latency of asbestos exposure. In this population of 121 workers, 94.2% were reported to have a radiologic diagnosis of asbestosis.[2] Later, in a 1979 report of 359 present and retired shipyard workers with at least ten years of exposure, 44% had parenchymal interstitial disease.[3] More recently, a population of electricians with at least twenty years of union membership, the prevalence of small opacities was 2.1%.[4] These reports show the dramatic decline in dust-induced lung disease. We do recognize the problems in comparing prevalence rates in populations with different lengths of latency; yet, these numbers reflect important changes in the outcome of workers with potential exposure to asbestos. Yet, even with the most recently reported diminished prevalence rates, we cannot dismiss the rate of occurrence of these illnesses.

What caused this dramatic lessening in the number of cases of asbestosis? Regulatory agencies have become sensitized to the adverse respiratory effects of asbestos exposure and responded by lessening permissible exposure limits. Decisions made by governmental agencies regarding standard setting have been driven by epidemiologic studies. These studies have used years of employment and dust measurements as variables and the development of disease (as manifest by decrements in lung function tests [typically, the Forced Expiratory Volume in One Second (FEV_1) and Forced Vital Capacity (FVC)] and the development of chest radiographic [as interpreted by the International Labour Organization (ILO) classification] abnormalities. The notion that these variables determine outcomes in a relatively predictable manner (i.e. dose-dependent) is a key to protecting the worker. Using these data workers have been protected. Yet, summaries by American governmental agencies reflect the continuing adverse effects of dust exposure on the American worker (Fig. 110.1).

Our challenge is not only to detect clinical illness early, but to educate potentially exposed workers and their families about the health risks of asbestos. Prevention of these illnesses will be accomplished only by substituting safe materials and by limiting asbestos exposure in the workplace by appropriate engineering controls.

ASBESTOS FIBERS

Asbestos is classified as serpentine or amphibole, based on structural and chemical properties. Chrysotile is a serpentine asbestos and accounts for 95% of world production. The fibers are long, silky, pliable and heat resistant, but poorly resistant to sea water and chemical digestion. Because of its flexibility, it is commonly woven into textiles. The larger deposits are in Russia's Ural Mountains and in Quebec, although some is found in Vermont. Amphibole asbestos, in contrast to serpentine, is straight and rod-like and resistant to acids, heat and alkali. Crocidolite, amosite and anthophyllite are the common commercial varieties of amphiboles. Crocidolite and amosite are mined in South Africa, and anthophyllite is found in Finland. In Quebec, the asbestos deposit contains 99% chrysotile and 1% tremolite, making this deposit unique. Chrysotile, crocidolite and amosite are the most commonly used fibers in industry. Among the three amphiboles, anthophyllite is used least in commercial preparations due to the short and brittle nature of the fiber.[5]

A summary of its uses throughout time is of interest.[6] Since the beginning of the use of asbestos in industrial applications beginning around 1870, world annual asbestos production has increased from 500 tons until it approximated 5 million tons in 1975, the year of peak production. Since then, the health effects have been better understood and production has declined by 60%. Yet, 2003 statistics show that 2.15 million tons of chrysotile was mined.[7] Asbestos mining is typically an open pit operation where mechanical shovels and bulldozers mine and then load trucks or train cars for transport to a processing mill. The raw material is further processed by fracturing, sorting, and screening to separate the asbestos from undesired ores. Milling further concentrates the fibers by eliminating contaminants and sorting fibers by types and quality.

Although many manufactured products are composed of multiple fiber types, the longest asbestos fibers are used mainly for textiles insulation; intermediate length fibers are used in asbestos cement production and friction and filter production; while the shortest fibers are used in the vinyl asbestos tiles and as an admixture to industrial paints. Mill tailings from the mining process have been used in road construction. In past decades, the major end users have been the construction industry, the shipbuilding industry, and the automobile and railroad equipment industry. Today, much of the insulation and friction materials are made of non-asbestos replacement fiber materials. Potential worker exposures occur during mining, milling, handling, manufacturing processes, and particularly, during the destruction of previously manufactured material (asbestos abatement).

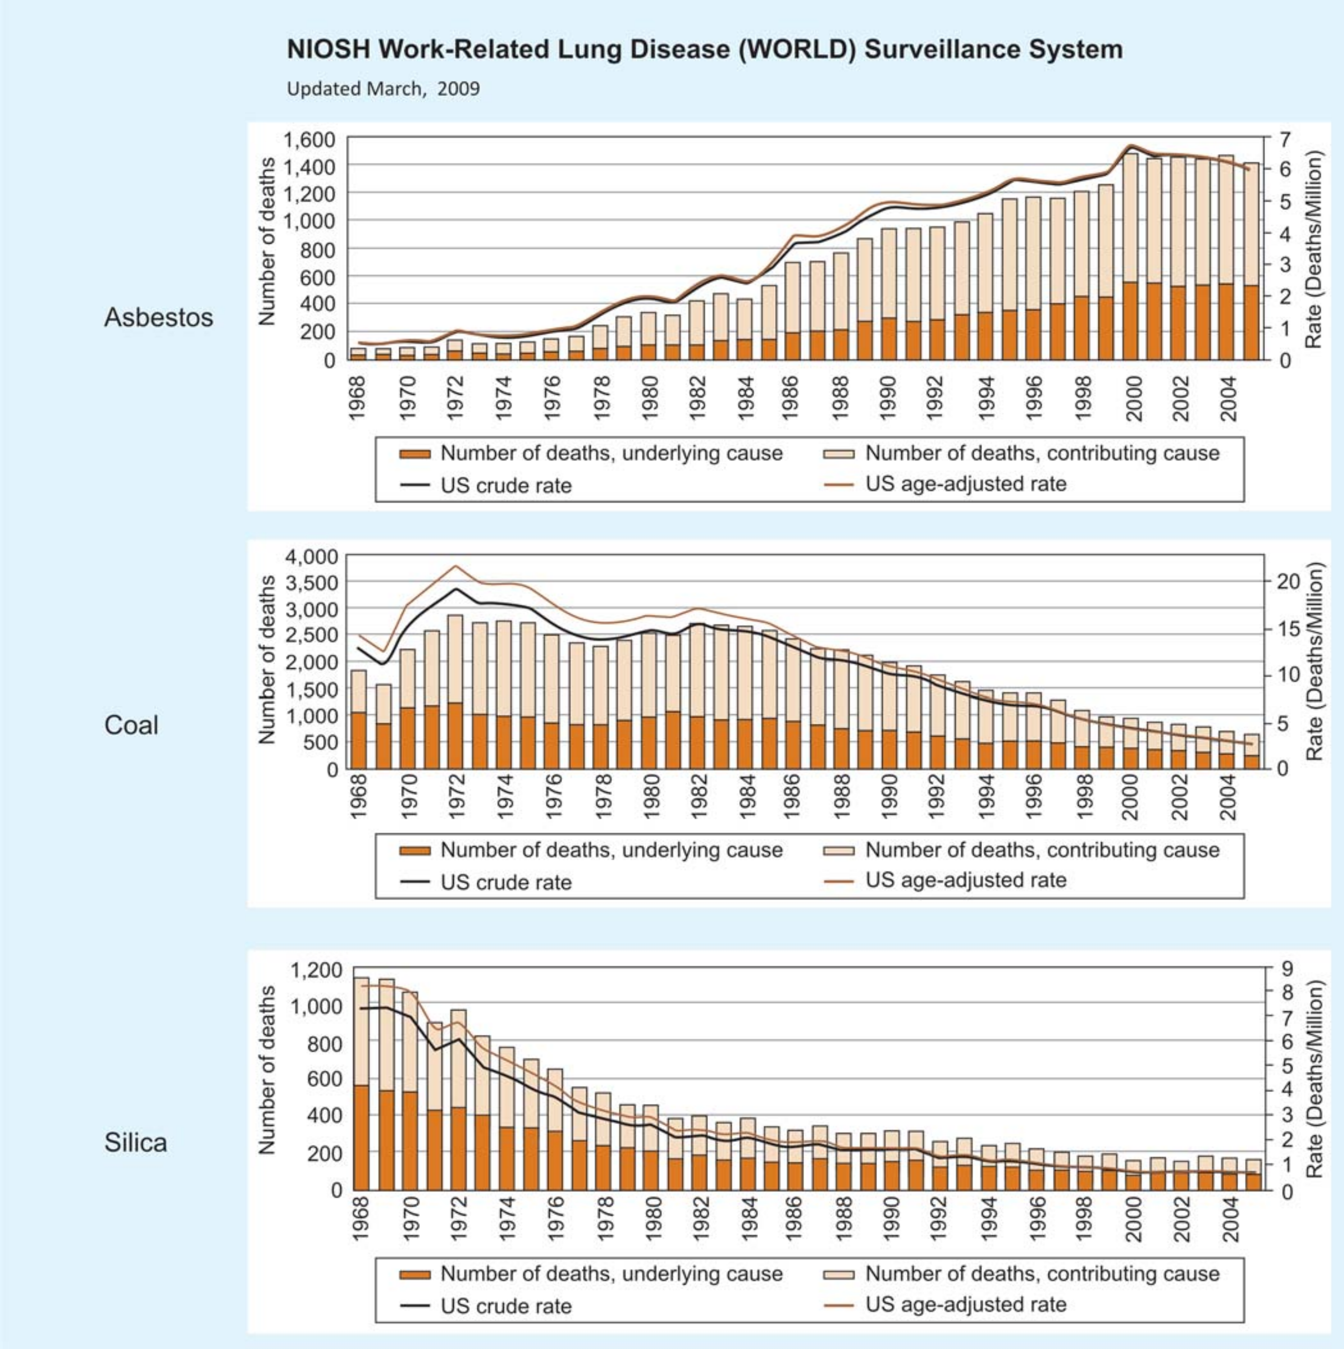

Fig. 110.1: Data from the US National Institute for Occupational Safety and Health show a continuing adverse effect of dust exposures on the health of the American worker. Although the mortality rates attributable to fibrogenic dusts have declined over time, asbestos exposure continues to have the most adverse effect on this population. Website http://www2.cdc.gov/drds/WorldReportData/referenced October 12, 2010

Asbestos is virtually indestructible and remains in the environment indefinitely. Once the fibers are incorporated into a manufactured item, there is little health risk unless the item is disrupted.

Parenchymal Penetration by Fibers

Asbestos fibers which are not cleared by airway cilia penetrate deep into the lung parenchyma. Crocidolite, the thinnest, penetrates deepest; anthophyllite, the widest in diameter, penetrates least; amosite is intermediate in size and penetration. When the chrysotile fiber is long, despite the similarity in diameter to crocidolite, penetration is less than expected due to its serpentine shape. Typically, fibers with diameters greater than 3 µm do not penetrate in the lower lung but those less than 3 µm may penetrate cell membranes, and be carried within the macrophages into the interstitium and pleural space. The length of the fiber is also important. Fibers less than 3 µm in length can be phagocytosed and carried to the lymphatics to be drained, whereas those longer than 5 µm are incompletely phagocytosed and remain in the tissue, sustaining the cellular and molecular events leading to disease. Long fibers are cleared less rapidly than short fibers.[8] For example, fibers that are most carcinogenic for developing mesothelioma have lengths more than 8 µm and diameters less than 0.25 µm.[9] Crocidolite is about 10 times more carcinogenic than chrysotile for mesothelial cells and crocidolite fibers are more prone to induce pleural fibrosis. Lung fibrosis, however, is equally affected by both types of asbestos fibers.[10]

Analysis of lung tissue with identification of asbestos fibers supports the usual clinical methods of diagnosing asbestos-related diseases. Fibers may remain imbedded in the lung for years despite macrophage attempts to engulf and surround them.[11] With time, fibers coated with acid mucopolysaccharides form a matrix for “iron deposition”. Coating of fibers is thought to decrease fibrogenicity. Light microscopy allows visualization these ferritin-protein coated fibers (typically >10 µm in length) which appear as relatively long bead-like structure. Sometimes referred to as “asbestos bodies,” these coated fibers are more appropriately termed ferruginous bodies, as other inhaled fibers (e.g. talc, fibrous glass, cotton and diatomaceous earth) are handled in like manner. Thus, coated fibers are not diagnostic of asbestos, although ferruginous bodies have most commonly been found to have an asbestos core.[12]

Although ferruginous bodies can be found in the lung tissue of virtually all of us, identifying these fibers in digested tissue, sputum, and cells garnered by lung lavage may provide a fundamental index of asbestos exposure.[13-14] In the sputum of asbestos workers, the quantity of ferruginous bodies present has been correlated with duration of asbestos exposure.[15] Ninety six percent of urban dwellers over age 40 had ferruginous bodies present in their lungs. The number of ferruginous bodies was greater in the lungs of blue-collar workers and, in particular, steel workers.[16]

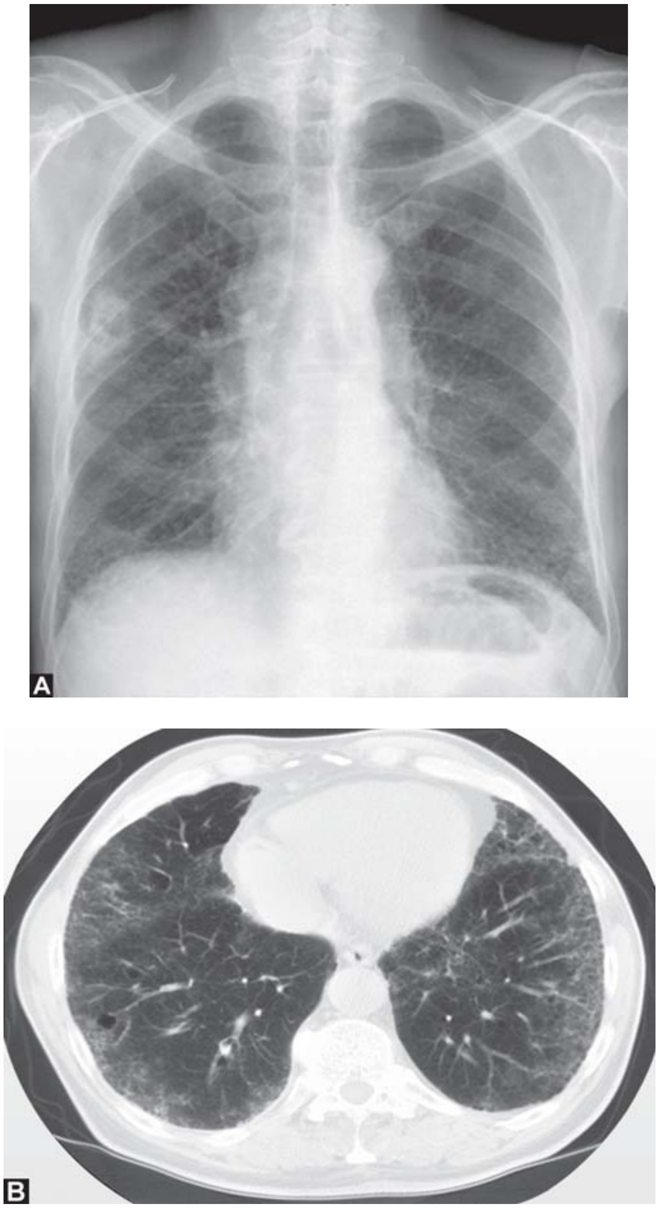
For nonfibrous minerals, it is unusual that particles exceeding 10 microns in diameter would reach the alveoli. Most particles deposited in the alveoli have a diameter of less than 5 microns.[17] However, these considerations do not apply to fibrous minerals such as asbestos. Fiber deposition in the lung is largely ruled by fiber diameter, with fiber length being less important. Fibers 200 to 300 µm long can be found in the lung as their diameter is less than 5 µm. The typical fiber-length of asbestos bodies is 20 to 50 µm, although many fibers less than 5 µm in length can also be found.

Asbestos fibers induce fibrosis and cancers of the lung and pleura.[18,19] Fibrosis begins as an inflammatory reaction which evokes a repair process, resulting in persistent scarring. Cancers begin as a multi-step process in which the target cell Deoxyribonucleic Acid (DNA) suffers increasing amounts of damage (genetic mutations) through a variety of molecular injuries.[20] Experimental animal studies and *in vitro* studies of cell cultures have shown that all of the types of asbestos fibers can cause cell damage which, if sufficiently severe, results in cell death, gene mutation, chromosomal aberration, aneuploidies, and malignant cell transformation.

Asbestosis

Although the prevalence of asbestos-related diseases have become substantially less over time, health issues continue to be recognized, particularly in the older or retired worker. Perhaps the most consequential of these dust diseases is asbestosis, the only major pneumoconiosis to demonstrate an increase in mortality over the past decade.[21] Mortality from asbestosis peaks 40 to 45 years after the workers’ initial occupational exposure to asbestos.[22] Since asbestos consumption increased substantially during and after World War II, with a peak in 1975, followed by a steep decrease beginning in the 1980s, asbestosis-related mortality will remain with us and perhaps even increase for another decade.[23] Asbestos-containing materials that continue to be used in some workplaces and remain in buildings represent a potential risk for the next generation.

The term “asbestosis” refers only to parenchymal fibrosis associated with asbestos exposure. The chronic and progressive inflammation and injury produced by asbestos fibers continues from the time of exposure, through the subclinical phase, to the time when clinical disease is identifiable by the classic methods of chest X-ray and lung function testing, as well as by more investigational approaches such as High Resolution Computerized Tomography (HRCT) scan[24,25] (Figs 110.2A and B).



Figs 110.2A and B: Chest X-ray and CT scan of a 71 year old man with a lung nodule. (A) The chest radiograph shows increased interstitial lung markings at both bases. Mild honeycombing was noted. A cavitary mass is noted in the right upper zone. (B) Slices from the CT scan show fibrotic changes consistent with asbestosis

Signs and symptoms of asbestosis are those of the other diffuse interstitial fibrotic diseases, but may not be present or only minimally noted early in asbestosis. Dyspnea on exertion is the usual symptom of presentation, which worsens as the disease progresses and lung function declines. Non-productive cough and chest pain are present in some cases, but occur late in the disease. When the cough is productive, it is likely attributable to bronchitis. Chest tightness and chest discomfort can be attributed to muscle pain appearing only when the cough and the dyspnea become severe. Hemoptysis is not expected and should be fully investigated as it suggests lung carcinoma. All of these symptoms may occur during the working years or even begin after exposure has ceased, becoming clinically apparent only after retirement.[26]

Persistent crackles are the most important physical finding. They indicate that disease is present and their appearance coincides with detectable changes in lung function and chest radiograph abnormalities, in most cases. They are typically first heard in the lower lateral lung fields in the late-inspiratory phase, and, as the disease progresses, increase in amount to become audible in the mid- and late phases of inspiration. Other adventitious sounds are usually absent. Finger clubbing may be present but does not necessarily relate to asbestosis severity. Cyanosis and reduced chest expansion are late manifestations of the disease.

The diagnosis is clinical and requires a history of exposure with an appropriate latency period, chest radiographic features consistent with asbestosis,[27] and the absence of other illnesses which might explain the radiologic features.[28,29] Idiopathic pulmonary fibrosis or lung fibrosis attributable to connective tissue disease is often part of the differential diagnosis. Although signs and symptoms of lung disease and respiratory impairment may be present, this is not a requisite for the diagnosis (Table 110.2).

The chest X-ray classically shows irregular basilar opacities which, in time, may progress to honeycombing.

TABLE 110.2: Clinical manifestations seen in some patients with asbestosis

1. Subjective respiratory complaints
2. Restrictive pulmonary function tests (FVC < 80% predicted)
3. Finger clubbing
4. Basilar crepitations
5. Chest radiograph with increased basilar lung markings
6. Known asbestos exposure

It commonly takes 15 or more years of exposure for these parenchymal changes to become detectable on the chest roentgenogram. The radiographic specificity for asbestosis, which may be identical to other diffuse fibrotic processes, is enhanced when bilateral pleural thickening and, in particular, when pleural calcification accompanies basal fibrosis.

The use of the Computed Tomography (CT) scan has not been shown to be justified in the periodic examination of asbestos exposed workers, but it has a place in the clinical investigation of these individuals. For example, it can better define pleural based abnormalities. When lung cancer or mesothelioma is considered, the CT scan better defines the anatomic extension of disease. Compared to the conventional CT scan, HRCT scan has improved our assessment of the interstitium and allows us to better appreciate interstitial and emphysematous changes.[30] Although the pulmonary abnormalities seen on HRCT are non-specific and cannot be attributed to asbestosis without characteristic pleural plaques and/or a history of significant asbestos exposure, the HRCT scan in asbestosis shows characteristic features.

When asbestosis becomes clinically important, it is classically associated with restriction of lung volumes (TLC<80% predicted). Although a decrease in small airway flow rates, due to peribronchial accumulation of asbestos fibers with associated fibrosis, may occur, smoking plays an independent role in the development of airway obstruction in heavily exposed workers.[31-33] Serial follow-up of workers with asbestosis showed that the decline in FVC was more than expected due to aging alone. A fall in diffusing capacity was the most sensitive measurement of a decrement in lung function, while the FEV_1, peak flow rate and pO_2, showed little change over time.[34] Grossly, the extent of fibrosis in the asbestotic lung varies from minimal amounts at the bases (in a subpleural distribution) to a diffusely fibrotic, shrunken lung. Progressive massive fibrosis occurs rarely and, if present, suggests mixed dust exposure.

Microscopically, asbestosis is fibrosis associated with asbestos bodies (by light microscopy) or uncoated asbestos fibers (by transmission electron microscopy). Both fibers and fibrosis must be present. Dust accumulation and fibrosis occurs at the level of the respiratory bronchiole, and may have features thought to sometimes be consistent with respiratory bronchiolitis. The alveolar septae become thickened and infiltrated with mononuclear cells, neutrophils and macrophages. With progression, diffuse alveolar wall thickening occurs with replacement of parenchyma by collagen. The severity and extent of the asbestos induced fibrotic process in a lung specimen correlated with other parameters of disease severity, such as the radiograph and lung function tests.[35]

The most likely respiratory illness which can be mistaken for asbestosis is Idiopathic Pulmonary Fibrosis (IPF). There are several differences aside from the absence of asbestos fibers in IPF. First, the interstitial fibrosis of asbestosis is accompanied by very little inflammation; second, the fibroblastic foci that are seen in IPF, a disease with a much more rapid progression that asbestosis, is absent in asbestosis; and third, asbestosis is almost always accompanied by mild fibrosis of the visceral pleura, a feature that is rare in IPF.[36]

There are important questions concerning the development and progression of asbestosis. Specifically, is there an effective therapy? Does removing the worker with asbestosis from the work environment affect progression? Once recognized, asbestosis can be a chronic and progressive disease. The evolution of asbestosis has changed significantly since the original report in 1907 by Murray who reported 10 workers with asbestosis who died before age 30.[37] Corsican asbestos workers have been studied twice. First when almost 80% of the workers had no radiographic evidence of disease and later, despite no further exposure, when only 34% had no radiographic evidence of disease.[38] Epidemiological studies of asbestos exposed individuals beginning in the 1970s have repeatedly documented a higher incidence of asbestosis and lung cancer among workers with greater cumulative dose.[39] Currently, with improved industrial hygiene, the long latency period, and early disease recognition when there is only a minimally abnormal chest radiograph (ILO category 1 pneumoconiosis), most cases are recognized after age 50 and fewer than 20% of cases so, recognized progress.

The medical management of the patient with asbestosis is supportive. Steroids are not helpful. There is experimental evidence to support ceasing exposure reduces the rate of progression.[40,41] Once diagnosed, the worker must avoid further exposure to asbestos dust.

Pleural Effusions

Although the mechanism is not understood, pleural effusions can be attributed to asbestos exposure. These effusions may be clinically manifest as being without symptoms with radiologic features of a blunted costophrenic angle as the sole manifestation of the inflammatory process to a “full-blown” bout of pleurisy with chest pain on inspiration, fever, dyspnea and a substantial collection of hemorrhagic fluid in the affected pleural space. The effusions are exudative in nature and are typically a “diagnosis of exclusion.” These may occur in individuals who have a history of asbestos exposure and a latency period most often of approximately ten to fifteen years from initial exposure, although sometimes less (such effusions as recognized to be the earliest occurring among the numerous presentations of asbestos induced chest effect).[42] These may be attributed to asbestos after chemical and cellular assessment of the fluid in the pleural space, as well as a sample of the pleura, provides no clear diagnosis. This may require serial chest radiographs over an observation period of two or three years as these effusions typically resolve slowly and spontaneously over a period of months.[43,44]

Asbestos pleural effusions do not predict the development of lung cancer, pleural plaques or mesothelioma, although exudative effusions often accompany lung cancer as well as mesothelioma.[45,46] Not surprisingly, these exudative effusions leave a "scarred" pleural space as they resolve. This is manifest by the radiographic appearance of obliteration of the costophrenic angle and described as diffuse pleural thickening.

Diffuse Pleural Thickening: Fibrosis of the Visceral Pleura

Diffuse pleural thickening is a disease of the visceral pleura. It is not specific for asbestos exposure and is often associated with fibrosis due to an inflammatory reaction caused by tuberculosis, surgery, hemorrhagic chest trauma, or drug reaction. In addition the radiologic features of pleural thickening were more than three times more likely in obese (BMI > 30 kg/m^2) asbestos workers.[47]

In association with asbestos exposure, the mechanisms which cause diffuse pleural thickening are unknown, but it appears to be the result of exudative benign pleurisy in most cases. In other cases, where there is no history of a previous episode of benign pleurisy, perhaps the confluence of pleural plaques or the extension of subpleural parenchymal fibrosis into the visceral pleura has caused diffuse thickening. In the most aggressive cases, diffuse pleural thickening can extend into the interlobular spaces of the lung and affect the fissures, leading to restriction of lung expansion, even in the absence of interstitial lung fibrosis.[48] Although it had been originally thought that those who develop diffuse pleural thickening had greater exposure to asbestos than those who developed pleural plaques, no difference in asbestos burden in those with plaques vs. those with diffuse pleural thickening was shown by calculating exposure ratings from exposures in the trade within the shipyard and years employed in the trade[49] (Figs 110.3A to C).

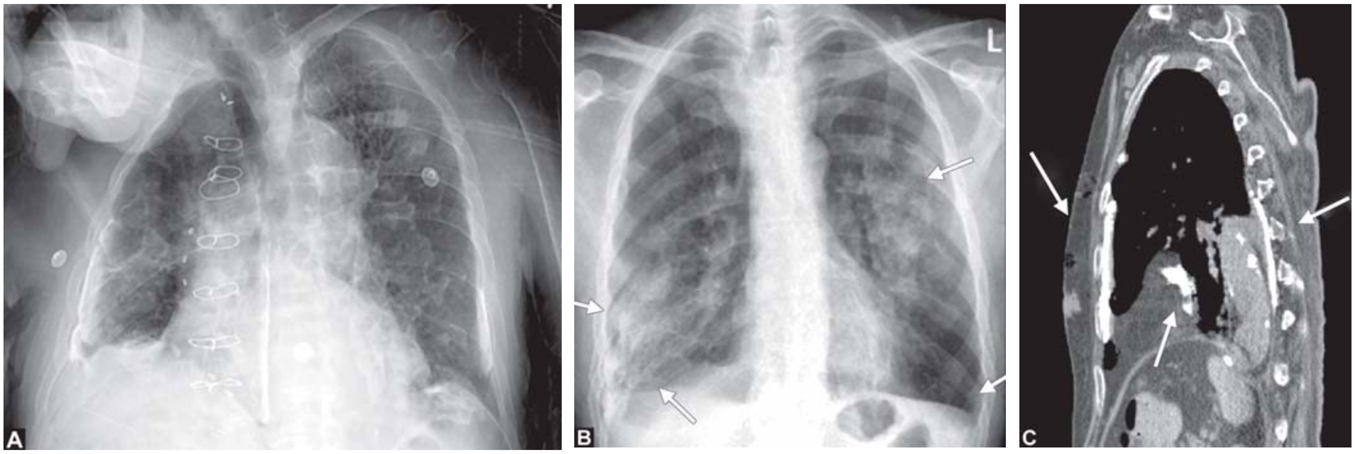
Diffuse pleural thickening may be responsible for dyspnea on exertion and perhaps a dry cough. Decreased respiratory excursion may be noted if the lung is "trapped" and moves little on the affected side. Diffuse pleural thickening may restrict lung function modestly if limited, but if extensive and bilateral, this may cause a significant restriction of lung function due to a "trapped lung" and result in respiratory insufficiency and failure in some instances. Although the radiographic features of diffuse pleural thickening often appear to show a more extensive pleural effect compared to the radiographic features of benign pleural plaques, data show no difference in mean exposures between workers with these two types of radiographic features. A wide distribution of exposures was recognized in both groups.

On the radiograph, diffuse pleural thickening appears as a continuous, smooth pleural opacity extending more than one-fourth of the pleural surface with blunting of the costophrenic angle. If diffuse pleural thickening is bilateral, the foremost concern is asbestos exposure. The relationship between these radiographic changes and asbestos is a clinical perception and does not require histologic confirmation unless malignant pleural disease is considered. Because this primarily affects the visceral pleura in the posterior and posterolateral lower zones, the CT scan provides a better visualization than the chest radiograph. Diffuse pleural thickening can be complicated by extension of fibrosis in the interlobar and interlobular fissures to form crow's feet (a focal abnormality of the visceral pleura which appear as small, pleural and parenchymal fibrous strands). Rounded atelectasis (the folded lung) is also known as Blesovsky's syndrome and is thought to be the result of visceral pleural fibrosis which has been "drawn back" into the lung.[50]

Pleural Plaques (Fibrosis of the Parietal Pleura)

One of the radiographic hallmarks of asbestos exposure is pleural plaques. These are located on the parietal pleura, are not associated with pleural adhesions, and cause no pulmonary function impairment. Workers with pleural plaques are without symptoms or signs of chest disease.

The pathogenesis of these plaques is unclear. Short and thin fibers are found in the pleural space soon after inhalation exposure. The most likely means of transport is via the lymphatics with probable additional contributions of gravity and respiratory motion.[51] Thomson has suggested that inhaled fibers gradually penetrate toward the base and periphery of the lung in a migration propelled by the continual movement of the lung.[52] He



Figs 110.3A to C: These three chest radiographs show features emphasizing diffuse pleural thickening. The first radiograph shows extensive pleural changes in an asbestos-exposed worker who has had previous coronary artery bypass surgery. Specifically, there is calcified pleural thickening in both right and left pleural bases and lower pleural margins. In addition, there are calcified *en face* pleural plaques most notable on the left chest and a discrete calcified pleural plaque along the left chest wall. The second radiograph shows extensive pleural calcifications with obliteration of both costophrenic angles. Particularly noticeable is a calcified discrete pleural plaque on the right chest wall. The final figure is a chest CT scan (sagittal cuts) showing heavily calcified pleural plaques on left side (along the anterior chest wall, the posterior and outlining the basal lobule). Calcifications of the descending aorta is also noted

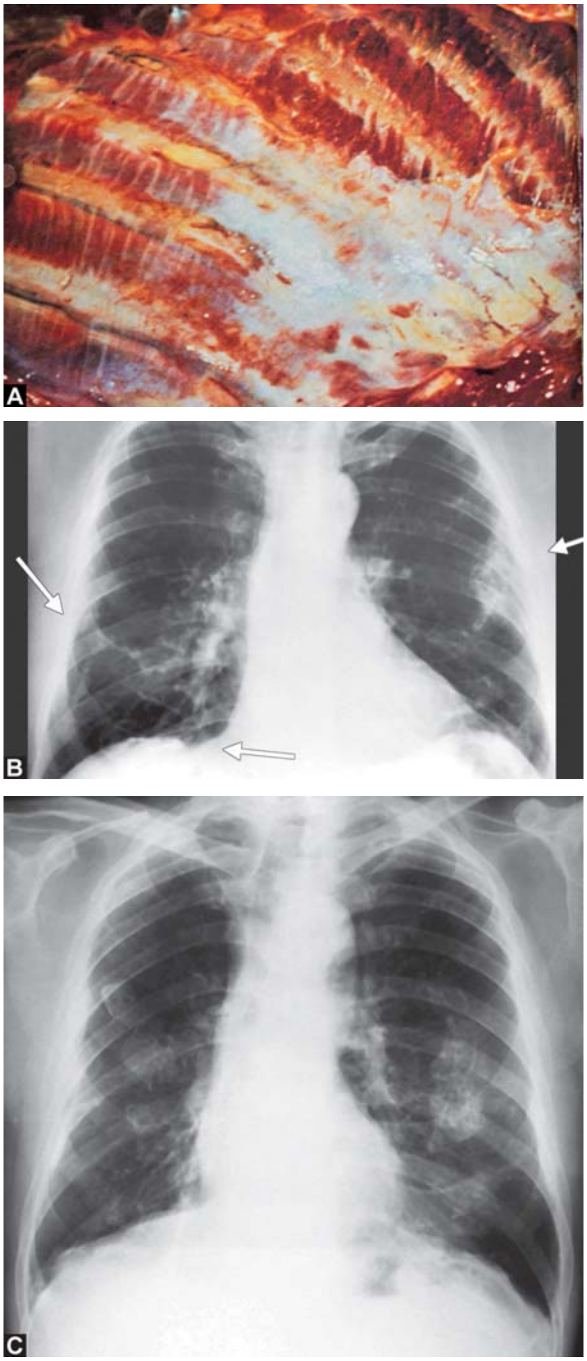
hypothesized that the common basal and posterior pleural plaques are a result of these areas being dependent when the subject is upright and during sleep. The tendinous part of the diaphragm, the ribs and the vertebral bodies block fiber penetration, and thus pleural plaques are typically located over these structures. Perhaps the thin and pointed nature of the fibers in the pleural space facilitate tissue penetration, scratching of the pleural tissue, and initiation of an inflammatory reaction, followed by organization, all leading to the pleural plaque. Even though pleural plaques are strongly associated with past asbestos exposure, they may occur in subjects with low-level or even sporadic asbestos exposure (based on fiber counts collected by broncho-alveolar lavage) using high resolution CT scans to identify the extent of fiber involvement.[53]

Grossly, plaques are firm, raised areas with a nearly white, glistening surface. Microscopically, collagen fibers are oriented in a parallel fashion in the sub-mesothelial layers of the parietal pleura at the level of the costal margins, the diaphragms, and the para-spinal areas. They are covered by a normal mesothelial lining which does not contribute to the development of the plaque. They can be found in the pericardium and, less often, in other mediastinal pleura. Visceral pleural plaques occur much less frequently, but can extend in the interlobar fissures. Therefore, the plaque is really extra-pleural.[54] This, plus the slow, nonexudative growth of the plaque may explain the lack of adhesions. Pleural calcification occurs in areas of collagen degeneration and implies that the plaque has been present for 20 or more years.[55] Generally, neither asbestos bodies nor asbestos fibers are found in the plaques. Although they serve as markers of asbestos exposure, there is no evidence to suggest that pleural plaques are premalignant forms of mesothelioma.

The earliest finding on the chest radiograph of a pleural plaque is frequently a thin line of soft-tissue density at the lateral margin of the seventh or eighth rib. This early change may be difficult to distinguish from normal "companion" shadows. The routine chest radiograph defines only 8 to 15% of all pleural plaques.[56] Oblique views may assist in their recognition. The conventional CT scan recognizes plaques much earlier and at a less well defined stage than the chest radiograph. Diaphragmatic plaques which were not always well appreciated with the conventional CT scan are better evaluated with the HRCT. Computed tomography scans can clearly differentiate plaques from extrapleural fat pads, a sometimes difficult distinction on the plain chest radiograph. Furthermore, in the presence of extensive and calcified pleural plaques, the CT scan permits a clearer appreciation of the lung parenchyma than the plain radiograph (Figs 110.4A to C).

Malignant Mesothelioma

Malignant pleural mesothelioma arises from the mesothelial cells of the pleura. Tumors may be solitary



Figs 110.4A to C: The first figure (A) shows a parietal plaque on the thoracic wall with an irregular thick plaque. (Photograph from the textbook Asbestos Related Disease: Clinical, epidemiologic, pathologic, and radiologic characteristics and manifestations. American College of Radiology, 1982). The first radiograph (B) shows pleural thickening along both lateral chest walls with shows a calcified pleural plaque of the right hemidiaphragm. The figure (C) shows several calcified *en face* discrete pleural plaques located on the chest wall, bilateral calcified pleural thickening along the lateral chest wall, and bilateral diaphragm thickening

or diffuse. Solitary mesotheliomas are benign, well-circumscribed, variable in size and usually fibrous in histologic type, although epithelial elements may be present. They are unrelated to asbestos exposure and curable by surgical excision. It is a rare tumor but with increasing incidence and a poor prognosis.

Diffuse mesothelioma has a gross appearance which is more diagnostic than its variable histologic appearance.[57] In its early stages, it appears as multiple gray or white nodules on the pleural surface (Fig. 110.7). It spreads along the pleural surface, encasing the lung with a resulting loss of volume. Distant metastases beyond the regional Iymph nodes are rare, unless advanced disease is present. The tumor has a predilection for growth along incision or biopsy sites. This malignancy spreads by direct extension into adjacent structures of the chest wall, interlobar fissures, lung parenchyma, mediastinum, pericardium, diaphragm, esophagus, large vessels of the mediastinum, contralateral pleura and the peritoneal cavity (Fig. 110.8). Death is usually caused by restriction of one or more of these vital structures. Malignant mesothelioma is of peritoneal origin in less than 25% cases. In the abdomen, the gross appearance of the tumor is quite similar with direct invasion of the abdominal structures. Microscopically, malignant mesothelioma may have one of three histologic patterns: Epithelial, sarcomatous or mixed. Usually, one pattern predominates, but elements of the other two may be present.[58]

Although inhalation of asbestos fibers is a major risk factor for the development of mesothelioma, not all mesothelioma are associated with asbestos fiber inhalation. Exposure to amphibole fibers is much more likely to induce mesothelioma than exposure to chrysotile fibers, yet all of the commercially available fibers have been recognized to cause mesothelioma.[59,60] The relationship between mesothelioma and asbestos exposure was first well documented in 1960.[61] A study of 17,800 asbestos insulators uncovered 66 mesotheliomas.[62] Most occurred 30 or more years from onset of exposure. Persons having household contacts with asbestos workers are at increased risk for development of mesothelioma.[63] Residents of communities where asbestos is mined/processed may also be at increased risk (Fig. 110.5). Mesothelioma is exceedingly rare in the non-asbestos exposed population, and the estimated mortality rate due to mesothelioma is one in 10,000 deaths per year in the general population.[64] Over-all, in the absence of asbestos exposure, malignant mesothelioma is a rare disease with an incidence of one to two cases per year per million people in the general population of North America.

Fig. 110.5: A 28-year-old accountant presented with dull chest pain for several months. Evaluation showed a large pleural effusion and diagnostic work-up showed malignant mesothelioma. Lung tissue assessed for asbestos fibers showed two different types in the lung. Importantly, when asked, she reported that she had recently finished her CPA (Certified public accountant accreditation) and had no known exposure to asbestos. The story was a puzzle until the MDs realized that her two places of residence in her life were several blocks from an asbestos cement manufacturing plant that had ceased operation in New Orleans several years earlier

Using the Louisiana state registry, we showed that there was a cluster of mesothelioma in women (but, not men) residing in this 70116 zip code in the previous decade, with a decrease in the number of cases as one went further away from this address. This led us to conclude, based on epidemiologic data, that the risk for developing mesothelioma may well have been associated with the presence of the asbestos cement plant in the residential area

In the asbestos exposed populations, the rates can be 5 to 20 fold higher, with a gradient of 10 to 1 for crocidolite to chrysotile exposures.[65]

Symptoms develop insidiously and include progressive dyspnea and weight loss. Most patients with mesothelioma cite chest pain, often only partially relieved by analgesics, as the reason that they consult a physician. The presenting sign is usually a unilateral pleural effusion. As the disease progresses, affected supraclavicular nodes may become palpable and ribs may become tender as a result of local tumor invasion. Both superior and inferior vena caval obstruction can occur with resultant congestion, edema, and ascites. Digital clubbing may be present.

Malignant mesothelioma should be considered in the differential diagnosis of all cases of explained exudative pleural effusion, particularly if asbestos exposure is documented. Clinical clues suggesting mesothelioma include contralateral pleural plaques and pleural calcification. In fact, among workers with asbestosis and/or asbestos-related pleural disease, there has been a significant increase in the risk for mesothelioma.[66-68] The issue under discussion, at least some of these reports, is the adequacy of accurately identifying plaques by chest radiograph.[69-70] Commonly, mesothelioma is seen in the absence of basilar interstitial fibrosis, a classic finding of asbestosis.[71]

During thoracentesis, it may be difficult to enter the pleural space due to thickened pleura. The effusion is exudative, viscous and very cellular, with normal, malignant and inflammatory cells. Cytologic examination of the fluid is often of limited diagnostic value because it is frequently difficult to differentiate benign from malignant mesothelial cells. Hyaluronic acid may be greatly elevated in effusions associated with malignant mesotheliomas.[72] Because of rapid fluid accumulation,

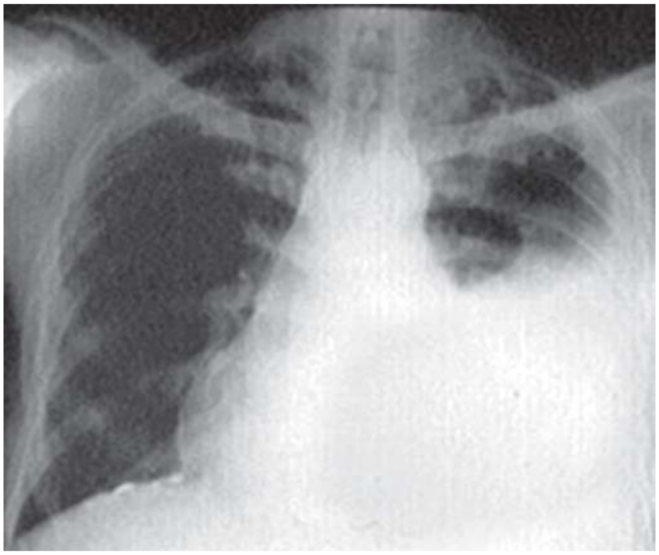

Fig. 110.6: This radiograph shows a large left-sided pleural effusion. Following thoracentesis, the left lateral chest wall showed a "bumpy" nodular appearance. Histologic staining of the mass showed malignant mesothelioma with associated. Note displacement of the heart to the right and calcifications on the right hemidiaphragm

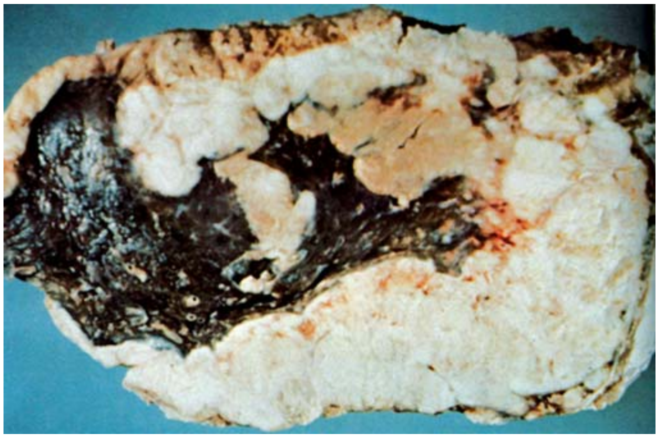

Fig. 110.7: This lung was removed at autopsy from an insulator with a 35 year history of asbestos exposure. The lung is encased by the gray-colored mesothelioma. (Photograph from the textbook Asbestos Related Disease: Clinical, epidemiologic, pathologic, and radiologic characteristics and manifestations. American College of Radiology, 1982)

repeated thoracentesis may be necessary to palliate dyspnea.

There is no method for the early recognition of mesothelioma. Although an open thoracotomy with pleural biopsy may well be needed to provide adequate amounts of tissue to establish a certain diagnosis, recent recommendations suggest that an earlier and equally reliable diagnosis may be gained through the use of thoracoscopy (except in cases of pre-operative contraindication).[73] In addition, because standard staining procedures are insufficient in approximately 10% of cases, these consultants propose using specific immunohistochemistry markers on pleural biopsies. No staging system exists for mesothelioma. The authors propose use of the most recent TNM-based classification for lung cancer for mesothelioma and propose a three step pre-treatment assessment. The patient's performance status and histological subtype are currently the only prognostic factors of clinical importance in the management of Malignant Pleural Mesothelioma. Other potential parameters should be recorded at baseline and reported in clinical trials. Malignant pleural mesothelioma exhibits a high resistance to chemotherapy and only a few patients are candidates for radical surgery. To date, surgery, radiotherapy, chemotherapy, and, of late, immunotherapy or cytokine therapy, or a combination of the above, have been equally unsuccessful in curing this disease although may improve prognosis for a period of time. Gene therapy has not yet reached clinical practice.[74] Patients who are considered candidates for a multimodal approach to therapy should be included in a prospective trial at a specialized center.

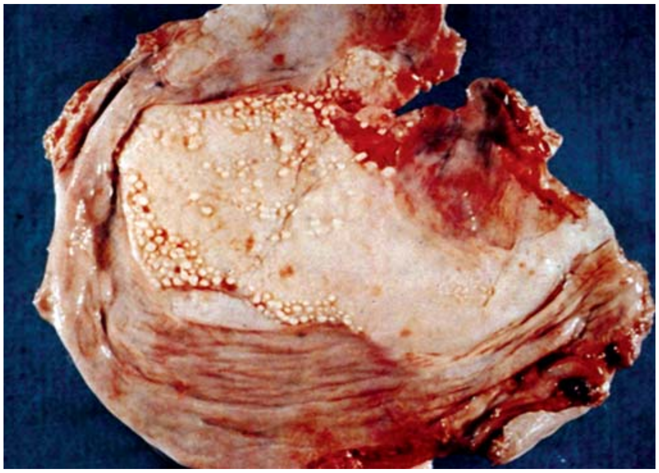

Fig. 110.8: This photograph shows the peritoneal surface of the diaphragm of a pipefitter with a 30 year asbestos exposure history. The main tumor mass was within the peritoneal cavity and involved the small intestine and pelvis. The discrete white nodules reflect seeding of the mesothelioma along the inferior aspect of the diaphragm. (Photo from the textbook Asbestos Related Disease: Clinical, epidemiologic, pathologic, and radiologic characteristics and manifestations. American College of Radiology, 1982)

Lung Cancer

An association between asbestos exposure and bronchogenic cancer was first suggested in 1935, and, since that time many studies have documented this relationship.[75] The persistence of asbestos in the lung parenchyma results in a lifelong exposure to this carcinogen. Thus, despite removal of the worker from a contaminated environment, the worker's lungs are continually exposed and the risk for cancer increased. In a series reported several years ago, 60% of English workers were disabled due to asbestosis and died of lung cancer.[76]

Our understanding of the way that asbestos induces lung cancer is incomplete.[77] Some consider asbestos to be a tumor promoter on the basis of its weak activity in standard tests which address a carcinogen's potential (i.e. its ability to produce chromosomal abnormalities). Based on this perspective, the fibers increase the susceptibility of the lung to other carcinogens. Others consider asbestos to be a tumor initiator and note the excess number of lung cancers in animals not exposed to other carcinogens and the excess of lung malignancies in lifetime non-smokers. A separate, and quite contentious issue, reflects whether asbestosis is necessary for the genesis of lung carcinoma. This is supported by epidemiological studies which have shown an excess number of lung cancers in a great majority of reports addressing the outcomes of the most heavily exposed workers with the highest prevalence of radiographic opacities consistent with asbestosis.[78] However, alternative views contend that lung cancers occur in the absence of radiologic or histologic evidence of asbestosis and that the extent of asbestos exposure, the risk for developing asbestosis, the effects of cigarette smoking and the ensuing risk for lung cancer all run parallel and increase with time, making the measurable risk for asbestosis alone, as it applies to lung cancer, difficult to separate from these other parameters.[79-82] Discussion continues on this topic.

Our understanding of asbestos-related lung cancers in the absence of clinically recognizable asbestosis is further complicated by the multiplicative risk of smoking. In another study of the same workers, the risk of lung cancer in cigarette smoking asbestos workers was compared to a group without asbestos exposure.[83] Asbestos workers who smoked one pack of cigarettes per day had an 87 fold increase in the risk of developing lung cancer compared to nonsmoking, non-asbestos exposed controls. In nonsmoking asbestos workers, this risk was only five-fold. This has led to the postulate that the exposure to smoking and to asbestos causes a multiplicative risk for lung cancer. More recently, data from different asbestos exposed populations and the risks for lung cancer were measured. Although the fiber dose required to develop lung cancer was similar among different populations of asbestos insulators, it was very different among populations of workers exposed to asbestos in the manufacture of textiles and in workers employed in the manufacture of asbestos cement. The disparities are not clear and have led many to challenge the hypothesis that there is not a "multiplicative risk," but rather a synergistic effect of asbestos exposure and cigarette smoking altered by other interacting elements in the causation of lung cancer. Rather suggestions regarding smoking history; fiber type; underlying obstructive lung disease; exposure to contaminant metals, ionizing radiation, and chemicals such as benzopyrene and polycyclic aromatic hydrocarbons; the presence or absence of asbestosis and the question of individual susceptibility have been considered as possible explanations for these differences.[84]

Asbestos-related cancers are not distinct in type, nature, or their location within the lung from those solely associated with cigarette smoking. The histologic distribution of asbestos-related cancers approximates 35% epidermoid, 25% small cell, 30% adenocarcinoma and 10% large cell carcinoma, a distribution similar to the cell types of cancer in those who smoke without asbestos exposure.

Asbestos-related lung tumors present in the same manner as lung tumors caused by other carcinogens, except when the symptoms of asbestosis are present. In the presence of asbestosis, it is accepted that lung cancers should be compensated. In the absence of asbestosis, compensation has been debated, some refusing compensation for all cases, others favoring compensation for cases of long exposure (about in excess of 20 years). A detailed discussion of this is beyond the scope of this review.

An Assessment of the Extent of Asbestos-Related Disease in India

Compared to the United States, where a great amount of asbestos was used during World War II and continued to be used until the 1970s, a significant amount of the consumption of asbestos in India began later on. In the US, annual consumption approximated 40,000 metric tons in 1920. This gradually increased to 100,000 metric tons by 1940, and then increased again to 500,000 tons yearly from 1950 until 1970 with the peak being 803,000 tons in 1973. Asbestos has not been mined in the United States since 2002, so the United States is dependent on imports to meet manufacturing needs. Asbestos consumption in the United States in 2009 was estimated to be 715 tons. Roofing products were estimated to account for about 65% of US consumption and other applications, 35%.[85]

In India, the timeline is very different. In one report, approximately 125,000 metric tons were used in 1995 with a gradual yearly increase until utilization reached 200,000 tons consumption per year in 2003.[22] In a second report dated 2003, the annual consumption of asbestos in India was cited to be less and to approximate 100,000 metric tons. One-fifth of this amount was mined in India, with the rest being imported, a great percentage from Russia and Canada.[86] A more recent unofficial report stated that India's asbestos use has risen to 300,000 metric tons yearly. Importantly, since 2003, companies no longer need a license to import chrysotile, so it may be more difficult to track usage.[87] A great percentage of the asbestos used in India is mixed with cement to form roofing sheets. Although the epidemic of asbestos-related disease in the US appears to be slowing, this pattern of asbestos usage suggests that the Indian epidemic is closer to its beginning.

In the absence of banning the use of asbestos, control of asbestos dust exposure in the workplace is the most effective way to prevent disease. In the past, although peak asbestos fiber counts in the workplace air sometimes exceeded 100 fibers/cc of air, more typical exposures ranged from 5 to 20 fibers per cc. The current allowable US limit to airborne exposures is 0.1 fiber per cc of air expressed as an 8 hour time-weighted average with a maximum exposure of limitation of 1.0 fiber per cubic centimeter of air (1 f/cc) as averaged over a sampling period of 30 minutes for all fiber types.[88] In India, asbestos exposure is regulated under the Factories Act (1948), in which asbestosis is listed as a notifiable disease in the schedule 3 of the Act.[89] Under this act, the limit of exposure is 1 f/cc. Asbestos is also regulated under the Environment Protection Act (1986) which sets a limit of 4 f/cc. for environmental emissions.[90]

Two reviews provide considerable insight into the prevalence of asbestosis in India, although in other reports, authors are increasingly vigorous in maintaining that asbestosis occurs much more commonly than it is reported.[87,91-94] One report states that as of 2005, approximately 100,000 workers have been exposed to asbestos, and less than 30 workers have been compensated. This same report recognized 41 workers with asbestosis in one asbestos processing plant where asbestos brought into the workplace in bags is processed and made into finished products such as asbestos textiles and brake and clutch linings.[95] A 1996 epidemiologic study reported lung impairment and radiologic abnormalities in 54.8% of asbestos millers and 19.5% of asbestos miners.[96] In some workplaces exposures are excessive. In a study of asbestos cement factory workers, exposures were two to three times higher that the Threshold Limit Value (TLV) among asbestos pipe cutters, but below the TLV in other areas. In this group, the FVC was less in the group employed 16 to 20 years, but in workers employed more than 20 years, the mean values of all pulmonary function parameters studied were reduced, implying a "mixed" defect in lung function. When smokers were compared to non-smokers, there was no measurable effect.[97] In another report of asbestos miners, exposures were below the permissible exposure limit in the mine, but the ambient exposures in the mill were 200 to 400 f/cc.[98] These exposures were lessened to 15 to 20 f/cc. with appropriate engineering controls.[99] Others have reported grossly increased exposures in asbestos milling.[100] With such exposure data it is not surprising that a 1989-1990 report by the Indian National Institute of Occupational Health (NIOH) showed an asbestosis prevalence of 4% among miners and 21% among millers.[101] The prevalence of asbestosis in asbestos cement factories and the asbestos textile industry workers is variably described from 3% to 9%.[102,103]

It has been very difficult to estimate the predicted number of mesothelioma cases and when these cases may reach their peak. In the US, about 2,000 annual deaths from mesothelioma are anticipated in coming years. This year, in 2010, approximately 700 cases are anticipated in Australia. In the Netherlands, it has been predicted that pleural mesothelioma will peak in 2028, with nearly 900 cases. In France, the number of annual deaths attributable to mesothelioma is expected to peak in 2020 at 2,200 cases.[104] Unfortunately, with the lack of reliable reporting of diseases such as mesothelioma and the continuing use of asbestos, it is not possible to make such assessments in the Indian population.[105] Yet, it is reasonable to be concerned that this disease will persist.

CONCLUSION

To begin, the reader should be reminded that the best indicator of past asbestos exposure (the gold standard) remains the detailed work history. If the exposure history is not clear, the presence of pleural abnormalities of diffuse pleural thickening or pleural plaques can serve as a surrogate for past asbestos exposure. In the rarest of occasions, an open lung biopsy with assessment of the mineral content of the lung is possible.[106]

Although a great number of articles address the adverse respiratory health effects associated with asbestos exposure, numerous questions regarding the determinants of pleural disease (specifically, mesothelioma and pleural plaques) and how fibers interact with the pleural space remain. Specifically, why some workers with similar workplace exposures have very different radiographic manifestations is not understood. Some develop pleural plaques, while others may have an exudative pleural effusion which may end up with diffuse pleural thickening. How do pleural plaques develop when there is only minimal evidence of inflammation in the pleural space? How does the persistence of fibers in the lung of one worker result in mesothelioma while in another there is no visible effect?

Next, it is reasonable to state that there is a sufficient amount of data to justify the current exposure regulations which protect the worker from the development of asbestosis. Yet, there is no exposure evidence available which addresses the maximal allowable levels of asbestos exposure which will protect the worker from the development of pleural changes, mesothelioma, or the risk of lung cancer. Asbestos exposure regulations are not based on these features of exposure.

Finally, it remains unclear how asbestosis apparently transforms into lung malignancy. Yet, even more unclear is how fibers which may cause inflammation, but no discernable lung disease, increase the risk of malignancy.[107] Overall, this appears to be increasingly consequential. In the past, the weight of evidence about the relationship between asbestos exposure and lung cancer appeared to favor the conclusion that asbestosis was necessary to attribute lung cancer to asbestos exposure. At present, this conclusion has been increasingly challenged as research continues.

Occupational Asthma

Gajanan S Gaude

INTRODUCTION

Physicians commonly encounter patients who develop or show increased severity of asthma during their adult working life. It is important to determine in these situations whether work is causally related to the development of asthma. Indeed, asthma is now the most common cause of work-related respiratory disease in the industrialized countries. Occupational asthma in fact is a silent disease, frequently seen, but seldom considered. Occupational asthma is estimated to constitute an average of 15% of adult asthma and an even more of new-onset asthma in adults.[1]

HISTORICAL ASPECTS

Ramazzini provided clinical descriptions of Baker's asthma and farmer's lung in his treatise, "De Morbis Artificum" in 1713. Only in 1920s, greater details on occupational asthma appeared with the recognition that exposure to many substances, such as hay, grains, pollens, dusts and animals could provoke the attacks of rhinitis and wheeze. The term "occupational asthma" was coined by Von Pirquet in 1906. These disorders were attributable to the proteinaceous High Molecular Weight (HMW) or Low Molecular Weight (LMW) reactive chemicals. Following the World War II, the surge in the industrial growth led to the introduction of a plethora of reactive chemicals into the workplace leading to an increase in the symptoms of occupation-related asthma.

DEFINITIONS

Occupational asthma is characterized by wheezy breathlessness occurring after exposure to a sensitizer at work. It may also include subjects with prior asthmatic symptoms whose symptoms subsequently worsen as a consequence of sensitization in the workplace. It is defined as a disease characterized by variable airflow limitation and/or Nonspecific Bronchial Hyperresponsiveness (NSBH) due to causes and conditions, which are attributable to a particular occupational environment and not to stimuli encountered outside the workplace.[2] It includes both the immunological and nonimmunological causes:

i. Immunological occupational asthma occurs upon exposure to an agent after a latent period of immune sensitization.
ii. Nonimmunological asthma may or may not occur after a latency period of exposure to an agent(s), which does not induce immune sensitization as determined by currently available technology. It has also been defined by the presence of reversible obstruction of the airways associated with bronchial hyperresponsiveness caused by the inhalation of dusts, gases, fumes or vapors that are produced at or incidentally present at the workplace.[3] It excludes bronchoconstriction caused by exercise or cold air. Preexisting asthma does not preclude the development of work-related asthma.

The American College of Chest Physicians (ACCP) consensus statement on occupational asthma tries to differentiate between work-exacerbated asthma and occupational asthma.[4] Work-related asthma is a broad term that refers to asthma that is exacerbated or induced by inhalation exposures at the work place. The term "work-exacerbated" asthma refers to asthma triggered by various work-related factors (e.g. aeroallergens, irritants or exercise) in workers who are known to have preexisting or concurrent asthma (e.g. asthma that is occurring at the same time, but is not caused by workplace exposures.) Occupational asthma refers to asthma or the recurrence of previously quiescent asthma (e.g. asthma as a child or in the distant past that has been in remission) induced by either sensitization to a specific substance [e.g. an inhaled protein (HMW protein of > 10 kd) or a chemical at work (LMW agent)], which is termed sensitizer-induced occupational asthma or by exposure to an inhaled irritant at work, which is termed irritant-induced occupational asthma.

Sensitizer-induced occupational asthma presents with a latency period includes those causative agents (proteins and some chemicals) for which sensitization can be demonstrated (typically by antigen-specific IgE) in most persons with asthma due to exposure to that agent. It also incorporates occupational asthma caused by those agents (usually reactive chemicals) for which an immunologic mechanism is strongly suspected, yet an antigen-specific immune response cannot easily be tested in most of the affected workers. The most definitive form of irritant-induced asthma is Reactive Airways Dysfunction Syndrome (RADS), which is described as acute onset of asthma after a single, very high irritant exposure. Work exacerbated asthma and occupational asthma may coexist in the same worker. In contrast to work-exacerbated asthma, the onset of asthma due to work exposures in a person with a history of asthma in the past or during childhood is considered more likely as the new-onset occupational asthma and not work-exacerbated asthma; the recurrent onset of asthma unrelated to work and subsequent work exacerbation is also possible.

EPIDEMIOLOGY

It is the most common form of occupational lung disease in many Western countries, having overtaken the pneumoconiosis owing to improved control of exposure to silica, asbestos and coal dust. There are no long-term prospective studies that deal with occupational asthma. Nearly all the epidemiologic studies have relied on subjective data in identifying asthma. It has generally been accepted that at least 9 to 15% of adult asthma can be attributed to work place exposure, although recent data indicate that 25% or more of de novo asthma may have occupational basis.[5,6] The reported incidence of occupational asthma was 13 cases per million workers in South Africa, while it was approximately 6% of all asthma patients in a large university hospital respiratory clinic in Zambia.[7] Statistics from around the world indicate that a high percentage of adults with asthma miss work in a 12-month period because of their asthma: 25% in the United States, 17% in Western Europe, 23% in Central and Eastern Europe, 27% in Asia-Pacific and 30% in Japan.[8] Incidence of occupational lung diseases, including occupational asthma in India is on the rise.[9] Indian industry remains labor intensive, often employs relatively inexpensive and hazardous technology due to financial constraints. This is especially true for the unorganized small scale sector. There are very few studies on the prevalence of occupational asthma in India. A clinical survey done in two silk filatures industry revealed that 36.2% of the persons engaged in the processing of natural silk suffered from bronchial asthma, while 16.9% of the total subjects had asthma of occupational origin.[10] The overall prevalence data remains underestimated principally because of the lack of an appropriate reporting system.

WORK-EXACERBATED ASTHMA

Work-Exacerbated Asthma (WEA) is a condition associated with the worsening of asthma attributable to workplace conditions. It occurs among people with asthma whose onset occurred before entering the suspected job (i.e. preexisting asthma) or while in the suspected job, but with onset not attributable to workplace conditions (i.e. coincident or concurrent asthma). Symptoms can be confounded by exposures to cigarette smoking (or other irritants) or in association with hobbies or businesses run from homes that have irritating or allergenic environmental stimuli. Work-exacerbated asthma may account for much greater morbidity and productivity losses than occupational asthma.

AGENTS CAUSING OCCUPATIONAL ASTHMA

Occupational asthma may encompass both immunological and nonimmunological causes:[11]

i. Immunological (allergic) occupational asthma occurs upon exposure to an agent after a latent period of immune sensitization to a substance or material present at the work site characterized by variable work-related airflow limitation and the presence of specific/nonspecific airway hyperresponsiveness. In sensitized subjects, reexposure to a small amount of the causative agent leads to the occurrence of asthma.

ii. Nonimmunological (nonallergic) occupational asthma is due to an outstanding workplace irritant exposure and develops without a preceding latent period of exposure to an agent(s), which does not induce immune sensitization and is distinguished by persistent nonspecific airway hyperresponsiveness. This category includes irritant-induced asthma or RADS, which may occur after a single or multiple exposures to nonspecific irritants at high concentrations.[12] Two distinguishing features are pertinent to this classification of occupational asthma – latency and specific airway reactivity. In RADS, the exposure is characteristically acute, singular and extreme in nature, but asthma developing after lesser exposures and occurring over a more prolonged period of time has been intimated. In both allergic and nonallergic asthma, pathologic changes depict bronchial mucosa injury and inflammation.[13]

The major risk factor for occupational asthma is the extent of exposure to the sensitizer. The workplaces that allow high and frequent exposure of workers to airborne sensitizers may expect a high rate of respiratory problems. Atopy increases the risk of an individual becoming sensitized and contributes to an early sensitization and early occurrence of symptoms.[14] Smoking increases the risk of sensitization and the development of IgE antibodies.[15] The diagnosis should be confirmed objectively.

Most of the occupational agents causing asthma have known or suspected allergic properties. These agents are divided into two groups: those with HMW and those with LMW (< 1,000 daltons).

High Molecular Weight Compounds

Occupational agents, such as the proteins, polysaccharides and peptides induce allergic response by producing specific IgE antibodies and sometimes, specific IgG antibodies (Table 111.1). In most instances, positive immediate skin test reactions can be elicited and specific IgE antibodies to these antigens can be demonstrated. These patients are usually atopic with the history of allergic rhinitis or eczema. They usually describe asthma symptoms occurring within a few minutes of exposure. There is a good evidence to suggest that specific IgE antibodies to the hapten-protein conjugate are responsible for the patients' symptoms. Occupational asthma due to IgE-dependent etiological agents mostly affects the atopic subjects.

1. *Animal Products:* Laboratory animals are commonly used for experimental purpose. The most common cause of asthma is rats, followed by mice and rabbits. The allergens are usually found in the excreta and secreta of these animals.[16]
2. *Plant Proteins:* Dock workers are exposed to various cereals that can cause, apart from occupational asthma, different syndromes as a result of exposure to organic dust, including allergen-induced airway obstruction and a febrile alveolitis-like condition. Cereals and flours along with isocyanates are the old agents known to cause respiratory symptoms. Wheat is the most commonly incriminated cereal, but soya is also highly allergenic. Bakers are at the risk of developing sensitization not only to various cereal flours they handle at work, but also to storage mites, various other added protein products and enzymes (á-amylase is the most common) that are added to offer better control of processing.[17] Other food additives, such as hemicellulase and papain, used as enzymes in bakeries, can also cause sensitization.

   Gums derived from plants contain high polymer carbohydrates that produce mucilages when they react with water. Common examples include gum acacia or arabic gum, used in the food and pharmaceutical industries; tragacanth, used mainly in printing; karaya, grown in India and used instead of tragacanth. Guar gum, another natural gum, is reported to be responsible for asthma in the carpet-manufacturing industry.[18]
3. *Enzymes:* Association of exposure to detergent enzymes with asthma, nasal and ocular symptoms among workers involved in the manufacture of detergents has been known for several years. These workers show positive skin test reactivity to *Bacillus subtilis alcalase* and develop an immediate or late asthmatic reaction on inhalation challenge.[19] Various occupational allergens of plant and flower origins, beans and gums, can cause occupational asthma. Many ubiquitous allergens can, at times, be considered as occupational allergens. This is the case of grass pollens for municipal workers cutting lawns or mites for hotel employees making beds.[10]
4. *Fish Proteins:* Workers at food processing units develop occupational asthma. Oyster handlers are found sensitized to the "hoya" or "sea-squirt" contaminating oysters, and develops symptoms of rhinitis and asthma. Processing of prawns and snow

TABLE 111. 1: Occupational allergens: High molecular agents

Class	*Agent*	*Occupation or Industry*
Animal proteins	Laboratory animals (hairs, urine, serum, pelts)	Drug, research, breeders
	Bovine proteins	Dairy workers
	Egg white/yolks	Egg processing workers
	Prawns	Prawns workers
	Crabs, prawns, sea squirt	Snow crab workers
	Chicken	Poultry workers
	Pigeon, parakeets	Breeders
	Salmon, trout	Food processing
	Horses	Veterinarians
Plant proteins	Cereal grains, grain dust	Granary workers, millers
	Wheat and rye flour	Bakers, millers
	Buckwheat	Food processors
	Hydrolysed gluten	Food workers, bakers
Enzymes	Subtilisin	Detergent
	Trypsin (hog)	Drug
	Pancreatin	Drug, medical
	Bacillus subtilis	Food processors
	Fungal amylase	Bakers
	Flaviastase	Pharmaceutical
	Pepsin	Pharmaceutical
Legumes	Coffee beans	Food processors
	Soybeans	Farmers, dockworkers
	Castor beans	Fertilizer workers
Seeds	Cotton seeds	Bakers, fertilizer workers, cottonseed oil producers
	Linseed	Linseed products
	Flaxseed	Flax workers
	Tea leaves	Tea processing workers
Insects and ascarides	Grain mites	Granary workers, farmers, dock workers
	Silk (silkworm moth, larvae, eggs)	Sericulture industry workers
	Maggots	Fisherman
	Mealworms	Bait/grain workers
	Cockroaches	Laboratory workers
	River fly	Power station workers
	Locust	Laboratory workers
Enzymes (plant)	Papain	Food processors
	Bromelain	Food processors
Vegetable gums	Gum acasia	Confectionary, pharmaceutical
	Karaya	Food, hair dressers
	Tragacanth	Printing, hair dressers
	Guar	Carpet manufacturing
	Quillaja	Saponin workers
Miscellaneous	Grains	Farmers, distribution workers
	Tobacco leaf	Tobacco farmers and processors
	Garlic	Food workers
	Latex	Surgical gloves manufacturers
	Psyllium	Pharmaceutical
	Fungal spores and antigens	Farmers, biotechnology

crabs can lead to occupational asthma due to the inhalation of vapors released during boiling.

Low Molecular Weight Compounds

Many low molecular weight compounds (MW<1,000 daltons) have been shown to cause occupational asthma in various industries (Table 111.2). In some instances, the compounds have been shown to act as haptens that combine with carrier protein molecules as allergens. The most well-known compounds in this group include acid anhydrides, metals, such as platinum and some pharmaceutical products.

1. *Wood Dusts:* Many different species of wood have been identified as being associated with occupational asthma. Western red cedar is the most common wood dust studied and is the most common type of occupational asthma in the Pacific Northwest. Red cedar asthma affects 4 to 14% of the exposed population, depending on the type of industry and the level of dust exposure.
2. *Metals***:** Exposure to metals may occur not only in metal mining and metallurgical industries, but in a number of other trades, such as welding and soldering. Platinum-induced asthma has been recognized for a long time. Platinum salts, particularly the halides, are more potent in inducing sensitization and asthma than any other metallic salt. In some chemical plants, the cumulative risk for sensitization can be as high as 51% within five years.[20] Smoking is a strong risk factor for a positive skin prick test and predisposes for the development of asthma. A variant of occupational asthma has been reported among pot room workers in aluminum smelters who report respiratory symptoms during a shift at work. The cause of pot room asthma is not known. The occurrence of nickel-induced asthma compared to contact dermatitis among exposed workers is rare. Exposure to zinc and chromium can also lead to asthma in addition to contact dermatitis.
3. *Diisocyanates:* Diisocyanates are used extensively in a number of important industries all over the world. They are used in the production of rigid and flexible foams as protective coatings for electric wiring, for painting automobiles, as adhesives and binders in foundries, as liners for mine and grain elevator chutes, soles of shoes and spandex fibers. All these chemicals have N=C=O groups that are highly reactive and explain their sensitizing properties. The prevalence of diisocyanate-induced occupational asthma is from 5 to 10%.[14] Bronchial biopsies of patients with diisocyanate-induced asthma have shown absence of bronchial IL-4 RNA message, irrespective of response to inhalation challenge, suggesting that this is a non-IgE-mediated disease. Specific IgG and monocyte chemoattractant protein-1 have also been incriminated.
4. *Fluxes:* Colophony is widely used as a flux in electronic industry. Colophony is obtained from pine trees containing abietic acid. The prevalence of work-related respiratory symptoms among electronic workers was 22% and was related to the degree of exposure.[21] Half of the workers with colophony-induced asthma continued to have symptoms even four years after the cessation of exposure.
5. *Anhydrides:* Acid anhydrides are used in making alkyd and epoxy resins. Epoxy resins are widely used in adhesives, casting, coating and sealants, whereas alkyd resins form the base for paints, varnishes and plastics. Acid anhydrides can give rise to hypersensitivity reactions in the exposed population. Phthalate anhydride has long been known to cause occupational asthma and rhinitis. Trimellitic anhydride exposure is associated with asthma, rhinitis, late respiratory systemic syndrome and pulmonary disease-anemia syndrome.[22]

PATHOGENETIC MECHANISMS OF OCCUPATIONAL ASTHMA

Occupational asthma is probably the result of multiple genetic, environmental and behavioral influences and has serious medical and socioeconomic consequences. There are two basic variants of occupational asthma based on its pathogenesis. The allergic variant can be further divided into classic IgE-mediated and polyimmunologic forms. The nonallergic variant can be divided into reactive airways dysfunction syndrome, pharmacologic bronchoconstriction and reflex bronchospasm. Even if the precise causative mechanism of occupational asthma is unknown, several mechanisms have been proposed, i.e. immunological, pharmacological, genetic, and airway and neurogenic inflammation. More than one mechanism may be operative in occupational asthma.

Immunological Mechanisms

Immunologic mechanisms seem to be operative in most of the cases of occupational asthma. In fact, occupational asthma caused by the exposure to HMW compounds is mostly IgE-mediated, while those due to the exposure to LMW compounds is rarely so. During the latency

TABLE 111.2: Occupational allergens: Low molecular agents

Class	*Agent*	*Occupation or Industry*
Wood dusts	Western red cedar (plicatic acid)	Carpenters, saw mill workers
	African maple, ramin wood	Wood workers
	California red wood	Wood workers
	Oak	Wood workers
	Mahogany	Wood workers
Antibiotics	Penicillin	Pharmaceutical
	Spiramycin	Pharmaceutical
	Tetracycline	Pharmaceutical
	Cephalosporins	Pharmaceutical
	Methyldopa	Pharmaceutical
	Piperazine hydrochloride	Chemist
Metal salts	Platinum salts	Platinum refining
	Cobalt	Hard metal workers
	Nickel	Metal plating, welding
	Chromium	Cement tanning
	Aluminum	Aluminium refining
	Vanadium	Vanadium refining
Anhydrides	Phthalic anhydride	Plastics, drugs
	Trimellitic anhydride	Epoxy resins, plastics
	Tetrachlorophthalic anhydride	Epoxy resins
Diisocyanates	Toluene diisocyanate	Isocyanate and urethane manufacturing, adhesives
	Methylene diphenyl diisocyanate	Foundry workers, polyurethane foam
	Hexamethylene diisocyanate	Paint, plastics
	Naphthalene diisocyanate	Plastics
	Iosophorone diisocyanate	Plastics
Dyes	Azo- and anthraquinone, methyl blue, black G-R	Cloth dying
	Paraphenylene diamine	Fur dying
	Persulfate, henna	Hair dressing
Chemicals	Formaldehyde	Laboratory workers
	Glutaraldyhyde	Laboratory workers
	Cyanoacrylate esters	Adhesive use
	Azodicarbonamide	Foam manufacturer
	Formalin	Fur, tanning, insulation
	Hexachlorophene	Hospital staff
	Paraphenylene diamine	Fur dyers
Insecticides	Organophosphates	Farmers, manufacturers
	Pyrethin	Fumigation
Fluxes	Colophony	Electronics
	Amino ethyl ethanolamine	Aluminium soldering
	Fluoride	Aluminium refining
Miscellaneous	Sulfonechloramide	Pharmaceutical, cotton
	Piperazine hydrochloride	Pharmaceutical
	Alpha methyl dopa	Pharmaceutical
	Ethylenediamine	Hair dressing, plastics, rubber
	Ammonium thioglycolate	Beauty operators

period, allergens are processed by alveolar macrophages that present the antigens to the T-helper cells that in turn stimulate B cells to produce specific IgE. Sufficient quantities of antibodies are generated to sensitize circulating basophils as well as the mast cells.[23] High molecular weight agents act as complete antigens, whereas LMW chemicals must first react with autologous or heterologous proteins to produce a functional allergen. Crosslinking of allergens with a specific IgE antibody on the surface of mast cells, basophils and possibly macrophages, dendritic cells, eosinophils and platelets gives rise to a cascade of events that is responsible for inflammatory cell activation. There is subsequent synthesis and/or release of preformed and newly formed inflammatory mediators that then orchestrate the inflammatory reaction.

Pharmacologic Mechanisms

Certain agents in the work place may directly induce bronchoconstriction. Exposure to organophosphates, inhibitors of acetylcholinesterase, causes immediate symptoms of asthma. It has also been suggested that some agents, such as isocyanates and plicatic acid, act through a pharmacological mechanism. Isocyanates may act as beta-2-adrenergic blocking agents and plicatic acid is able to activate complement. The clinical importance of pharmacological mechanisms in occupational asthma is unclear. It is likely that the pharmacological properties of some of the agents in the work environment may interact and potentiate the immunological response in these individuals.[24]

Neurogenic Inflammation

The beta-adrenergic receptor is closely associated with adenylatecyclase, an enzyme present in the plasma membrane of many cells that indirectly controls processes, such as active secretion, transport and storage of carbohydrate. Mast cells in the lungs of asthmatics may have lower concentration of cAMP, which results in the release of the vasoactive mediators that cause asthmatic reaction. An abnormality in the beta-adrenergic receptors has been noted in patients who had asthma from toluene diisocyanate. In addition to the cholinergic and adrenergic mechanisms, Nonadrenergic-Noncholinergic (NANC), neural pathways involving the sensory nerves have been shown to be important in human lungs.[25] This network of unmyelinated sensory nerves contains potent peptides, including substance P, neurokinin A and a calcitonin gene-related peptide. These neuropeptides may play a role in the development of airway inflammation. Dusts, chemicals and other irritants stimulate the sensory nerves to release substance P and related neuropeptides. It has been observed that airways of patients with severe asthma do not contain Vasoactive Intestinal Peptide (VIP) in bronchial mucosa. The absence of this peptide, which is known to relax airways, could amplify the effects of constrictor agents. Inflammatory cells (mast cells, eosinophils, neutrophils) release numerous peptidases that rapidly breakdown VIP. This may be like "taking the brakes off" cholinergic nerves, resulting in an exaggerated reflex cholinergic bronchoconstriction, and contributes to bronchial hyperresponsiveness.[26].Tachykinins (TK) have the ability to affect multiple cells in the airways and to cause responses, such as cough, mucus secretion, smooth muscle contraction, plasma extravasation and neutrophil adhesion. These effects are termed "neurogenic inflammation".

Excitatory neuropeptides, including substance P, neurokinin A and calcitonin gene-related peptide are characterized by rapid onset smooth muscle contractile effects. They constitute unmyelinated sensory nerves and display inflammatory effects. Substance P causes airway smooth muscle contraction, stimulates mucus secretion, increases microvascular permeability and exudation of plasma into the airway lumen, degranulates mast cells, and possibly has chemotactic properties. Neurogenic inflammatory responses are presumably protective in nature. When neutral endopeptidase is inhibited by inhibitors or by exposure to cigarette smoke, respiratory viral infections or inhalation of chemicals (such as toluene diisocyanate), neurogenic inflammatory response is exaggerated.[27] Occupational stimuli which act on capsaic insensitive primary afferents and/or inhibit neutral endopeptidase, could trigger neurogenic inflammation and precipitate asthma.

Genetic Mechanisms

Some of the genetic abnormalities observed in occupational asthma, might provide a means to understand better the interaction between a susceptible genotype and multiple environmental factors. Several models of interactions have been proposed.[28] Not only the gene-environment interactions, but also gene-gene, gene-gene environment, and gene-environment-environment interactions may contribute to the risk of developing asthma. Genetic studies performed in platinum refinery workers suggested that the relative risk associated with the HLA phenotype was greater at lower levels of exposure, indicating that the strength of this association varies inversely with the intensity of exposure to the sensitizing agent.[29] It has been suggested that the most important gene variants for asthma are polymorphisms that exert their influence on the network system controlling biological responses to asthma-related exposures.[30] It has been proposed that specific HLA class II alleles could be involved in susceptibility or resistance to isocyanate-induced asthma, suggesting that the basic molecular and cellular mechanisms of occupational asthma induced by low molecular weight compounds are immunological, as in IgE-mediated asthma, in which the association with HLA class II genes is well-documented.[31] Occupational asthma induced by isocyanates and IgE-mediated asthma differs in terms of their association with particular HLA class II alleles or haplotypes.

DIAGNOSIS

A high degree of suspicion must be maintained in the evaluation of a patient of working age who develops asthma or notices a significant deterioration of preexisting symptoms. In most instances, the diagnosis of occupational asthma can be strongly suspected from the history alone, by finding a temporal relationship between symptoms and occupational exposure.

History and Physical Examination

The history should elicit the features of a work-related airway disease and provide clues to the linkage to one or more suspected work exposures. As expected, the history has a high degree of sensitivity but a low specificity for the diagnosis of occupational asthma. A thorough occupational history starts with a detailed chronologic history of the patient's jobs and exposures.

Patients with occupational asthma may have very typical symptoms of cough, wheezing, and dyspnea and may be able to associate the onset of symptoms to a specific exposure at the workplace. As the condition progresses over several months, symptoms tend to become more severe, to start earlier and last longer, to have nocturnal symptoms, and to impinge on the weekends. If the condition is not recognized and the cause eliminated, continued exposure will often lead to persistent severe asthma indistinguishable from that occurring in a nonoccupational asthma.[4] Remissions initially occur on holidays, but even this feature may disappear after a sufficiently prolonged exposure.

The physical examination may be specific but tends to be insensitive. It is important to establish objectively a relationship between work and asthma symptoms. Specific challenge tests or occupational exposure tests are often considered a reference standard for the diagnosis of occupational asthma. American College of Chest Physicians,[4] recommends that in individuals with suspected sensitizer-induced occupational asthma, in addition to carefully documenting the occupational history, one should perform additional objective tests when feasible (e.g. serial Peak Expiratory Flows (PEFs), serial methacholine challenges, immunologic assessments, induced sputum testing, and specific inhalation challenge testing) to improve the diagnostic probability. Since there are no physical examination findings specific for asthma and because work-related wheezing is difficult to detect, repeated pulmonary function testing (both at and away from work) is usually required in order to make the diagnosis of occupational asthma.

Pulmonary Function Testing

Pulmonary function studies are indispensable in the diagnosis and assessment of the severity of occupational asthma. Most importantly, there should be no doubt that reversible airflow obstruction exists. Before one can label a person suffering from occupational asthma, he should be diagnosed to be indeed suffering from asthma, which can be done by routine spirometry with bronchial reversibility pattern. A change of more than 15% in Forced Expiratory Volume$_1$ or Forced Vital Capacity (FEV$_1$ or FVC) from baseline values, or improvement in FEV$_1$>200 ml over baseline is the diagnostic of asthma. Once the diagnosis of asthma is achieved, the next important aspect is the documentation of work-related changes in pulmonary function. A single measurement of pulmonary function is not helpful in diagnosing occupational asthma. Pulmonary function measured on a day away from work may be normal in up to half of those with occupational asthma. Serial measurement of spirometry when the patient has been away from work for a time and repeated when the patient returns to work, if coupled with an appropriate change in symptoms, may help to confirm an association with the work environment.[32] Preshift and postshift measures of FEV$_1$ are not generally helpful to either confirm or refute a diagnosis of occupational asthma. The availability of portable, inexpensive devices has allowed physicians to monitor PEF at work and away from work. Coupling PEF monitoring and changes in Nonallergic Bronchial Responsiveness (NABR) for periods at work and away from work has also been proposed for the diagnosis of occupational asthma. A serial peak flow meter recording is most frequently used and is the most easily accessible test. The best time to identify changes in PEF from workplace exposures is when the patient with underlying asthma is as stable as possible. A more sophisticated method of analysis of PEFR, which is based on a computer-generated discriminant analysis (OASYS-2; OASYS Research Group, Midland Thoracic Society; Birmingham, UK) can also be used and this is now commercially available and uses a different method of plotting results.[32a]

The currently recommended method is for the patient to record his or her peak flow at least four times daily (on awakening, middle of work shift or lunch, end of work shift and before bed). At each time point, patients should perform the maneuver three times and record each result in a log. The optimal duration of the recording is for at least 2 weeks at work, including the weekends, followed by one to two weeks away from work. At present, a graph of the daily maximum, mean, and minimum flow is inspected visually to check for deterioration at work and improvement away from work. The results can be plotted and then visually interpreted to determine whether there is a pattern of worsened PEF during work weeks compared with days or weeks off work.

Nonspecific Bronchial Inhalation Challenge

The measurement of bronchial responsiveness may be beneficial in the assessment of the patient with occupational asthma. A positive challenge result supports a clinical diagnosis of asthma when baseline pulmonary function is normal. A negative study however, does not rule out asthma, particularly when the patient has been away from exposure for a period of time. Serial measurements of airway responsiveness in conjunction with prolonged recording of PEF provide the objective evidence of sensitization with the occupational agent. It can also serve as a good guide to the initial dose of occupational agent that can be safely given during a specific bronchial provocation test.

Skin Test and Serology

Skin testing with common allergens, such as the house dust, danders, and grass and tree pollens may be useful in determining the atopic status of an individual. In few circumstances, especially with high molecular compounds, appropriate extracts of potential occupational allergens are available for skin testing.[33] Skin testing with flour and wheat has a sensitivity of 96% and specificity of 81% for Baker's asthma.[34] Extracts of animal products, flour, coffee and castor beans have been shown to cause immediate skin test reactions in susceptible individuals. An important practical limitation is the general lack of standardized commercial skin test reagents for many occupational proteins. Nevertheless, non-standardized commercial reagents are widely available and can be used for skin-prick tests of food (e.g. wheat, rye extracts) and laboratory animals (e.g. mouse, rat and guinea pig).

Total serum IgE may be useful in monitoring the patients. The use of immunologic testing in the diagnosis of allergic occupational asthma is limited. Specific antibodies, such as IgE antibodies to various occupational allergens may be demonstrated by radioallergosorbent test and enzyme-linked immunosorbent assay. Although serologic testing is highly specific, it is often less sensitive indicator of sensitization than skin testing.

Specific Inhalation Challenge Testing

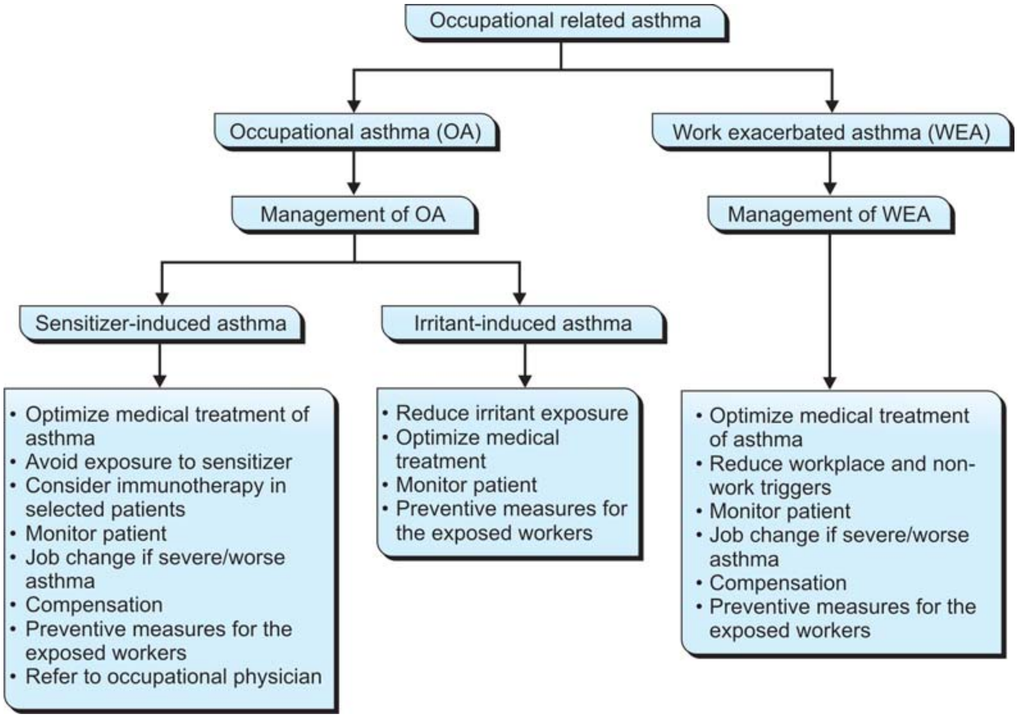
This test is still considered the gold standard in the confirmation of the diagnosis of occupational asthma. Originally performed in the laboratory and aimed at mimicking work exposure, it can also be done at the workplace. It is necessary to identify the substance at fault. In this test, the patient is exposed to the suspected sensitizer in a way in which he might be exposed at the workplace, although in a setting where symptoms are controlled and lung functions measured.

The most usual response to a challenge test is an immediate fall in flow rates, lasting for up to an hour. Typical patterns of bronchial reactions have been described.[35] Immediate reactions are those that shows maximal response 10 to 30 minutes after exposure, with complete recovery within one to two hours; they are actually the most dangerous, as they can be severe and unpredictable, stressing the importance of progressive exposure. Late reactions develop slowly and progressively, either one to two hour (early late) or four to eight hour (late) after exposure; they may occasionally be accompanied by fever and general malaise. They generally respond well to an inhaled beta 2-agonist, although the response may be of shorter duration in some subjects. Dual reactions can also occur.

In general, the diagnosis of occupational asthma can be firmly established in subjects who develop an asthmatic reaction with a greater than 20% fall in FEV, following exposure to sub-irritant level of an offending agent. However, a negative challenge test cannot exclude the diagnosis of occupational asthma with certainty.

MANAGEMENT

The algorithm for approach to the management of a patient with occupational asthma is shown in Figure 111.1. The mainstay of treatment of occupational asthma



Occupational related asthma
Occupational asthma (OA)
Work exacerbated asthma (WEA)
Management of OA
Management of WEA
Sensitizer-induced asthma
Irritant-induced asthma
• Optimize medical treatment of asthma
• Avoid exposure to sensitizer
• Consider immunotherapy in selected patients
• Monitor patient
• Job change if severe/worse asthma
• Compensation
• Preventive measures for the exposed workers
• Refer to occupational physician
• Reduce irritant exposure
• Optimize medical treatment
• Monitor patient
• Preventive measures for the exposed workers
• Optimize medical treatment of asthma
• Reduce workplace and non-work triggers
• Monitor patient
• Job change if severe/worse asthma
• Compensation
• Preventive measures for the exposed workers

Adapted from Reference no. 4

is prompt diagnosis and removal of the worker from further exposure to the inciting agent if substitution with a less hazardous substance is not possible. This is crucial in cases of sensitizer-induced occupational asthma, because even a very low exposure may trigger asthmatic reactions, including acute severe asthma attack. In most of the cases, the ideal solution is for the patient to be redeployed by the employer to a different work in a place where further contact with the sensitizer is not possible. If this is not possible, in many cases, the patient may need to work elsewhere, although this often entails financial hardship and an issue of litigation.[36] In some cases, workers with irritant-induced or work-aggravated asthma may continue to work in their usual jobs if the exposure to the inciting agent is diminished via proper engineering controls or by using respiratory protective equipment.[37] In the case of exposure to organic substances e.g. animal antigens and wood dusts, it may be possible to combine good local exhaust ventilation, partial enclosure of processes, and respirator use to reduce exposure, sufficient enough for the person to continue to work along with the use of medication. In such situations, patients should continue anti-inflammatory medicines and monitor their peak flow rates on regular basis. In cases of sensitization to LMW agents like isocyanates, acid anhydrides and colophony, redeployment or change of job is generally required.[36]

The management of occupational asthma does not differ significantly from the management of asthma that is not work related. The patient should be made aware of the need to balance future employment prospects against future risk. Once the diagnosis of occupational asthma has been made, the information should be given specifically (preferably in writing) to the patient who should be advised that the prognosis is improved by early complete removal from exposure. Continued exposure to the sensitizing agent may lead to greater airway inflammation and potentially, more airway remodeling and lower FEV_1.[38] When patient is unwilling or unable to leave a job, the initiation of anti-inflammatory and bronchodilator therapy may be the only management option available to the clinician, although the patient should be educated to understand that continued exposure may lead to a worse outcome; it is essential that patients have careful medical monitoring so that any worsening of asthma can be detected early and further interventions applied. It has been demonstrated that inhaled corticosteroids induce a small, but significant overall improvement in patients with sensitizer-induced occupational asthma after withdrawal from exposure. Inhaled corticosteroids have been found to be more beneficial if administered earlier rather than later after the diagnosis is established.[36]

Allergen immunotherapy is a possible treatment option for patients with sensitizer-induced occupational asthma, but there is limited evidence to support its efficacy.[39] Immunotherapy could be considered in settings where occupational asthma due to a specific allergen has been established, when only one or a few allergens are clinically linked to disease, when the avoidance of the triggering allergen is impossible, and when standardized allergens extracts are available for treatment. There are a limited number of studies of immunotherapy with allergens of potential occupational relevance such as for natural rubber latex for health care workers, venom from stinging insects for beekeepers, wheat for bakers, grass or ragweed pollen for outdoor workers and cat allergen for animal workers. Subcutaneous immunotherapy has been shown to be effective in reducing workplace symptoms, specific skin reactivity and medication use, but has not yet been shown to improve the clinical course of occupational asthma.[40,41]

PROGNOSIS

The long-term consequences of occupational asthma are variable and require prolonged follow-up. Symptoms due to occupational asthma may remit when the condition is diagnosed early and the worker is removed from further exposure. More commonly, the occupational exposure leads to persistent symptoms and permanent bronchial hyperresponsiveness.[42] A favorable outcome is noted with a shorter duration of symptoms before the diagnosis, relatively normal pulmonary function and a lesser degree of bronchial responsiveness. Persistent symptoms after the cessation of exposure were associated with a longer duration of symptoms, abnormal pulmonary function and more marked levels of bronchial responsiveness.

PREVENTION

As all occupational asthma cases are potentially preventable and given the high incidence of disease worldwide, better prevention efforts are required. Control of the exposures causing asthma is the most direct way of reducing the number of incident cases. No control measure can be assumed to eradicate asthma short of elimination of the causal agent.[43] Consideration should be given to the surveillance of exposed workers, especially in the first two years of work, preferably by a simple questionnaire of nasal and respiratory symptoms. [36]

Primary Prevention

Elimination of the sensitizing agent is the most secure way of preventing exposure. Substituting a new agent for the causative one in the workplace should be emphasized as the first step in the primary prevention. Other methods of primary prevention includes the reduction of exposure to the sensitizing agent, restriction of employment to the sensitizing environment, control of smoking and other respiratory irritants, and use of respiratory protection devices such as respirators.[43,44] Despite some important efforts with regard to HMW sensitizers, more exposure-response data on LMW sensitizers and irritants are critical to develop effective primary prevention programs. [45]

Secondary Prevention

Secondary prevention aims at early detection of asthma especially among workers in high-risk industries, such as the spray painting industry, where there is a high exposure to diisocyanates.[43] Periodic screening tests should be used to identify the persons at risk during the employment. A wide variety of questionnaires can be used for the symptomatology. Spirometry and immunological tests, where available, are to be used for the identifications of the asthma for the persons at risk.[4] Hence the main objective of secondary prevention is to evaluate the workplace to identify and prevent other cases of occupational asthma in the same setting.[46]

Tertiary Prevention

Tertiary prevention applies to individuals who have already been diagnosed with occupational asthma. It includes the institution of appropriate treatment and an effort to prevent permanent asthma by early removal from exposure.[47] Unfortunately, although this leads to symptomatic improvement, it may not prevent the development of persistent asthma.[48]

Another essential component in the prevention of occupational asthma is the surveillance for occupational asthma in the workplace. Risk assessment in the workplace is designed to minimize workplace risk associated with various hazards.[49] Engineering controls should be instituted in order to lower the risk of exposure to irritants and sensitizers, when substitutes cannot be found. Fundamental to this process is to identify all potential inhaled hazards and to assess the associated risk in that particular workplace. For example, isocyanate spray paints are hazardous when inhaled, but probably pose little risk when in solution form prior to activation.[50] It is the act of mixing these chemicals with an activator and aerosolizing these while spraying that is associated with a significant risk.

SUMMARY

Occupational asthma is currently the most common form of occupational lung disease in the developed world. The prevalence of this disease is likely to remain high for many years to come, because about 250 industrial agents are known to cause the disease and new chemicals are continuously being introduced into the workplace. Early in disease onset there is often an association with the workplace, although this relationship may wane over time and continued exposure. The diagnosis is generally established on the basis of suggestive history of a temporal association between exposure and the onset of symptoms and objective evidence that these symptoms are related to airflow limitation. Occupational asthma management differs from environmental asthma in two important ways. The first is the emphasis on functional outcomes. The goal and mark of successful therapy are improved work capacity and return to work. The second difference incorporates a public health approach to treatment. If the patient is exposed and has disease, then coworkers may also develop disease. Control of occupational asthma rests on the control of exposure by restricting the patient from direct or indirect exposure to the inciting chemical or process. Prevention of new cases is the best approach to reducing the burden of asthma attributable to occupational exposures.

Hypersensitivity Pneumonitis

PS Shankar

DEFINITION

Hypersensitivity Pneumonitis (HP) or extrinsic allergic alveolitis is a complex group of immunologically-mediated alveolar and interstitial lung disorders caused by repeated inhalation of a wide variety of airborne allergens. Several different kinds of environmental, occupational and recreational organic antigens, as well as the low-molecular weight chemical agents are responsible for hypersensitivity reactions in significant numbers of affected individuals to which they have been previously sensitized.

Most of these conditions exhibit similar clinical features, which develop several hours following environmental exposure.

HP was first observed by Jon Finsen in 1874 in the farmers of Iceland who inhaled hay that had been molded in the barn. Later, it was recognized in British farmers following work with hay and was described as farmer's lung in 1932 by Campbell.[1] Since the environmental antigens are ubiquitously distributed, this form of interstitial lung disease is more frequently recognized in the recent decades. New examples of HP are constantly being added due to changing environmental exposure.

ETIOLOGY

The inhaled antigens leading to development of HP can be classified as bacteria, fungi and their components (spores, mycelial fragments, degraded substrates and toxins), animal proteins and low-molecular weight chemicals (Table 112.1).

TABLE 112.1: Some of the common antigens responsible for different hypersensitivity pneumonitis

Causative agent	*Examples*
Bacteria	Thermophilic actinomycetes *Bacillus subtilis* *Klebsiella* spp *Pseudomonas* spp *Streptomyces alba* *Epicaceum nigrum* *Mycobacterium avium* complex
Fungi	*Aspergillus* spp *Alternaria* *Trichosporon cutaneum* *Cephalosporium* spp *Cladosporium* *Penicillium*
Animal proteins	Avian, Bovine, Porcine material, feather, silkworm larvae and insect material
Chemical sensitizers	Isocyanates, acid aldehydes, pyrethrum

A wide variety of antigens, usually organic compounds of biological origin from bacteria (thermophilic actinomycetes, *Bacillus subtilis)*, fungi (*Aspergillus* species, *Trichosporon cutaneum*) moulding stored vegetable matters (hay, barley, bagasse) and animal protein (avian, bovine, porcine or insect material) and reactive low-molecular weight chemicals used in industry, such as isocyanates are responsible for initiating hypersensitivity pneumonitis (Table 112.2). The changing practices of agriculture and industry have resulted in recognition of newer forms of HP.

TABLE 112.2: Common hypersensitivity disorders and their relationship to different exposures and antigens

Exposure	*Antigens*	*Diseases*
Mouldy hay[2]	Thermophilic actinomycetes	Farmer's lung
Mouldy bagasse[3]	Thermophilic actinomycetes	Bagassosis
Mouldy compost and mushroom[4]	Thermophilic actinomycetes	Mushroom worker's disease
Contaminated barley[5]	*Aspergillus clavatus*	Malt worker's lung
Compost[6]	*Aspergillus* spp.	Compost lung
Esparto grass[7]	*Aspergillus* spp.	Esparto dust lung
Soy sauce brewing[8]	*Aspergillus* spp.	Soy sauce lung
Contaminated humidifiers, air conditioners, heating systems[9]	Thermophilic actinomycetes	Ventilator lung
Domestic birds[10]	Bird proteins	Bird fancier's lung
Pigeon droppings[11]	Serum, feathers, droppings	Pigeon breeder's disease
Parakeets[12]	Serum, feathers, droppings	Budgerigar fancier's lung
Silkworm larvae[13]	Silkworm larvae proteins	Sericulturist's lung
Grains[14]	Grain weevil	Grain lung
Isocyanates[15]	Altered proteins	Hypersensitivity pneumonitis
Wood cutting[16]	Plant protein	Woodman's disease
Contaminated metal working fluid[17]	*Pseudomonas* spp	Machine operator's lung
Detergent enzymes[18]	*Bacillus subtilis*	Detergent worker's disease (washing powder lung)
Contaminated basement[19]	*Cladosporium* spp, *Penicillium* spp	Basement lung
Contaminated hot tub water[20]	*Mycobacterium avium* complex	Hot-tub lung
House dust[21]	*Trichosporum asahii*	Japanese summer house hypersensitivity pneumonitis

The risk of development of HP depends on the nature of inhaled antigen, the circumstances of exposure and the immunologic status of the host. The exposure is often to a complex mixture of antigens and not to a single antigen.[22]

The reaction occurs in a person, previously sensitized by exposure to the antigen and it does not depend on the constitutional makeup of the individual. The condition develops predominantly in non-atopic persons who may become sensitized to organic dust due to repeated exposure. An acute allergic alveolitis develops from exposure to high concentrations of antigen, repeated exposures to smaller amounts of dust is likely to cause chronic disease. The bacterial and fungal antigens found in the internal environment offer ideal circumstances for their proliferation. Inhalation of such material incites a hypersensitivity lung disease. Indoor bacteria (*Bacillus subtilis*), which thrive at lower temperature can lead to the development of HP.

Farmer's lung is the classical example resulting from exposure to mouldy hay, straw or grains. When the hay has been harvested while damp and stored under conditions of high humidity and temperature in barns and grain storage silos, it facilitates proliferation of the thermophilic actinomycetes-*Micropolyspora faeni* (now called *Saccharopolyspora rectivirgula*) in the organic matter. These spores are about 1 micron in diameter. The inhalation of dust from mouldy hay while feeding the live-stock, handling of mouldy straw or during threshing of mouldy grain crop, allows entry of the spores into the respiratory tract and their deposition in the alveoli in large amounts. The antigens liberated from such material leads to widespread reaction mediated by precipitins. The condition is seen in agricultural workers who handle mouldy hay or other mouldy vegetable products.

There are many similar diseases resulting from exposure to organic dusts. The thermophilic actinomycetes - *M. faeni* is considered responsible for bagassosis and mushroom picker's lung. The former appears following the inhalation of mouldy overheated sugarcane bagasse and the latter from mouldy mushroom compost dust. Those exposed to mouldy barley, mouldy cheese or coffee bean result in the manifestation of malt-worker's disease, cheese worker's lung and coffee worker's lung, respectively, where the *Aspergillus clavatus*, *Penicillium casei* and coffee bean dust act as sensitizing antigens.

People exposed to pigeon droppings and budgerigar (turkey pigeon) droppings are sensitized to avian serum proteins and result in pigeon fancier's lung and budgerigar lung disease, respectively. Improperly maintained or contaminated air conditioners or humidifier systems in offices and factories can provide a suitable environment for the growth of thermophilic actinomycetes.

HP induced by chemicals is relatively less common, compared to those induced by microbial and animal proteins. Isocyanates such as toluene diisocyanate (TDI), diphenylmethane diisocyanate (MDI), hexamethylene diisocyanate (HDI) and 1,5 naphthalene diisocyanate (NDI), used in the production of polyurethane polymers, are the commonly reported chemicals responsible for HP.

PATHOGENESIS

Pathogenesis of hypersensitivity pneumonitis involves a complex sequence of immunologic events in a susceptible and sensitized host. It does not develop on the atopic background. The condition is neither associated with eosinophilia nor raised levels of IgE. The sensitization results from an earlier exposure to antigen (organic dust). Following an intense reexposure to such an antigen, there is interaction of the antigen and the "memory" system. There is formation of precipitins and complement fixing antibodies and they form immune complex aggregates of antigen-antibody to bring about systemic and pulmonary reactions.

The demonstration of precipitins against the thermophilic actinomycetes in the serum and a delay of three to eight hours before the onset of symptoms following exposure to the antigen suggest that the pulmonary and systemic disturbances are as a result of an immune complex-mediated Arthus reaction. The immune complexes are not demonstrable in the alveolar septa or in the granuloma. It is considered that there is a mononuclear leucocyte-mediated component in the pathogenesis of HP.

A delayed type hypersensitivity reaction also to a certain extent is likely to be responsible for the development of chronic disease.[23] Animal models support the importance of cell-mediated immunity.[24] This view is strengthened by the presence of a higher proportion of lymphocytes in the bronchopulmonary lavage fluid. It implies that a local sensitivity may play an important role in the development of the disease.[25]

Though a large number of persons get themselves exposed to a given antigen and develop antibodies to that antigen, only a small number of them develop symptoms. Probably it is dependent on host susceptibility and the amount of antigen inhaled. The host susceptibility may also depend upon the differences in the persistence of noxious agent, environmental factors, the polymorphism and other genetic factors.[26-29] Some of the HPs, such as the farmer's lung are known to have familial aggregation, suggesting the importance of genetic predisposition.

PATHOLOGY

Following antigen exposure, the inhaled antigen reaches the alveolar space where it crosses the alveolar endothelium and binds to circulating antibody creating immune complexes that get deposited in the lung. There is an inflammatory response. The acute phase is mediated by neutrophils and the chronic phase by lymphocytes and macrophages in the form of a delayed-type hypersensitivity response. This is likely to lead to the formation of granuloma and progress to fibrosis.

Acute HP is characterized by diffuse alveolar damage with necrosis. There is an acute inflammatory infiltrate. Pathologic abnormalities are observed in subacute and chronic forms of the disease. Subacute form is characterized by the irregular areas of patchy consolidation with a centriacinar distribution. There are interstitial lymphocytic infiltrates, cellular bronchiolitis and loosely formed non-necrotizing granulomas. The small and poorly circumscribed granulomas consist of the aggregates of lymphocytes, plasma cells, macrophages and multinucleated giant cells. Presence of eosinophils and neutrophils are not characteristic. There is interstitial fibrosis with honeycomb changes in the chronic forms of disease. These changes are similar, irrespective of the causative antigens.

CLINICAL PRESENTATION

Hypersensitivity pneumonitis is a multifaceted clinical syndrome, which may mimic almost any interstitial lung disease, some infectious diseases and even bronchiolar disorders.[30] It presents predominantly with symptoms of dyspnea and cough. The condition may have an acute, subacute, or chronic onset. However, the manifestations frequently overlap. The manifestations are systemic and pulmonary. The systemic reactions are indistinguishable from that of infection.

High intensity short duration exposure leads to acute hypersensitivity pneumonitis. Acute condition presents with fever, chills, dyspnea, myalgias, arthralgias, headache, cough and chest tightness, 4 to 8 hours following a heavy exposure to the antigens. The symptoms peak in 6 to 24 hours following the exposure. Generally, the attack is self-limited and resolves in 1 to 3 days, following removal of the patient from the source of antigens. The continued exposure results in the persistence of symptoms. Physical examination usually reveals the presence of fever, tachypnea and bibasilar crackles.

The subacute form of disease is characterized by a slowly progressive symptomatology interspersed by discrete attacks of respiratory symptoms following heavy antigen exposure. In subacute form, the clinical features develop insidiously over a period of weeks. Cough and dyspnea are generally prominent. In some patients, the subacute form of the disease may permit the occurrence of an acute presentation especially if exposure to antigen persists.

In chronic condition, the level of antigen exposure is generally much lower and persistent. The respiratory manifestations develop slowly over months or years without any discrete attack suggesting the antigen as an offending agent. The patients suffer from increasing breathlessness, nonproductive cough and weight loss. Fever is usually absent. Examination reveals the presence of tachypnea and bibasilar crackles. Digital clubbing is uncommon. It is worth noting that the acute forms do not necessarily evolve into a chronic form of disease. It is intriguing why the consequences of antigen inhalation and the natural history of the disease process exhibit variations among individuals with the similar levels of the same antigen exposure. Moreover, only few individuals exposed to the antigens develop HP.

The clinical manifestations depend on the periodicity and the intensity of exposure. It may be either intermittent and heavy exposure or regular exposure in smaller dosages. Those who are exposed for limited duration intermittently to a relatively heavy concentrations of antigen as in the case of farmers involved with the mouldy hay and the pigeon fanciers engaged with cleaning of the pigeon lofts, manifestations that occur three to four hours after exposure reach a maximum in seven to eight hours and subside within 24 hours. The patient is able to associate his symptoms with the dust exposure. The incidence of serious disability can be stopped if the exposure is avoided or terminated. In those who expose continuously to smaller concentrations of antigen as seen in budgerigar fanciers, there is no acute history, and the features develop insidiously and progress to gross irreversible changes with fibrosis. The features of cor pulmonale and right ventricular failure ultimately supervene.

INVESTIGATIONS

Patients with acute HP exhibit polymorphonuclear leucocytosis without eosinophilia. Bronchoalveolar lavage (BAL) fluid shows the presence of neutrophils initially.[31] Later, it is replaced by lymphocytes. These lymphocytes are made up of $CD8^+$ lymphocytes.[32] During acute HP, there is increase in erythrocyte sedimentation rate and the inflammatory markers, such as the C-reactive protein. BAL lymphocytosis may persist for a long period of time after removal of antigen exposure.

The chest radiograph may be normal especially if obtained during an asymptomatic phase. In an established and symptomatic case, the radiograph shows the presence of patchy or diffuse infiltrates. Advanced cases exhibit pulmonary fibrosis with linear interstitial opacities, distortion, volume loss, and honeycombing. In acute HP, chest radiographs demonstrate a fine micronodular pattern or diffuse patchy ground-glass opacity.[12] They are characteristically seen in the lower lobes. These shadows resolve completely following cessation of exposure. HP is not associated with pleural effusions or thickening, and hilar or mediastinal lymphadenopathy. High resolution computed tomography (HRCT) is highly sensitive than the plain chest radiographs in detecting changes in the lung interstitium. It characteristically shows small, indistinct nodules, ground glass infiltrates and air-trapping.

In subacute form of disease, small nodules and fine linear opacities may be seen. In chest radiographs, chronic HP reveal the evidence of interstitial fibrosis manifested by diffuse linear and nodular radio densities. There is volume loss and honeycombing. These changes are predominantly noted in the upper lobes than in the lower lobes. There is evidence of pleural effusion or thickening. HRCT shows multiple, centrilobular nodules throughout the lung fields. These radiological ground glass opacities lead to volume loss and honeycombing.[33] Emphysematous changes may be seen in the lower lung zones in nonsmokers.

Exposure to an antigen is confirmed by the presence of elevated titers of serum antibodies (IgG, IgM and IgA). They can be demonstrated by utilizing ELISA, indirect immunofluorescence, complement fixation, latex agglutination or agar-diffusion methods. It suggests that the patient has been exposed to the suspected antigen and has mounted an immune response. The presence of antibody merely indicates the occurrence of exposure and sensitivity and not necessarily the disease.[34] It should be noted that the serum antibodies tend to disappear following the cessation of exposure to antigen. Several different cytokines involved in the disease pathogenesis have been demonstrated to rise in HP.[35,36] At present, they have no role in the diagnosis or clinical assessment of disease.

Pulmonary function tests may be normal or show restrictive, or mixed restrictive and obstructive patterns of defects. In acute HP, there is restrictive defect with a decreased forced vital capacity, total lung capacity and diffusion capacity. Mild obstructive defect may be seen due to bronchiolitis obliterans. The diffusing capacity is generally decreased. Arterial hypoxemia is evident especially after exercise.[37] The pulmonary function tests may be within normal limits in subacute HP. Chronic HP reveals both restrictive and obstructive defects. There is decreased diffusing capacity and hypoxemia. HP should be considered in differential diagnosis in nonsmoking individuals presenting with airflow limitation. Skin tests demonstrate immediate or delayed type of hypersensitivity against the suspected antigens. However, it has not shown its usefulness as often there are nonspecific reactions. Inhalation challenge tests for suspected antigens may be helpful in confirming the diagnosis.

Lung biopsies from patients with chronic HP show chronic interstitial inflammation with infiltration of plasma cells, macrophages and lymphocytes. They are found adjacent to the bronchioles. There are poorly formed, noncaseating granulomas without any necrosis. There may be bronchiolitis, bronchiolitis obliterans and sometimes with organizing pneumonia. In addition, there are varying degrees of interstitial fibrosis. Transbronchial lung biopsies may fail to provide sufficient material for the histopathologic study, open lung biopsy is preferred in such a situation.

DIAGNOSIS

The diagnosis of hypersensitivity pneumonitis is considered as one possibility in most cases of undiagnosed interstitial lung diseases. The patient has to be questioned about potential occupational and home exposures. A detailed history with special reference to the appearance of symptoms and the work history and activities of the person has to be obtained. History of exposure to pets (particularly the birds), chemicals used in gardening, and the details of indoor environment have to be obtained. Acute hypersensitivity pneumonitis is often confused with pneumonia, secondary to viral or mycoplasma infections. Recurrent episodes of similar symptoms should suggest hypersensitivity disorder of the lungs and search should be made for the relevant exposure. The clinical diagnosis of the HP is made on the basis of diagnostic criteria (Table 112.3). The diagnosis is confirmed if four major and at least two minor criteria are present, in the absence of other disease with similar findings.[38]

TABLE 112.3: Diagnostic criteria for hypersensitivity pneumonitis

Major criteria

1. History of compatible symptoms that appear or worsen within hours after antigen exposure
2. Exposure confirmation based on history, environmental investigations, serum precipitin testing and/or BAL antibody
3. Compatible abnormalities on chest radiograph or HRCT
4. BAL lymphocytosis
5. Compatible histologic changes on biopsy, and
6. Positive natural challenge(reproduction of symptoms and laboratory abnormalities after exposure to the suspected environment) or by controlled inhalation challenge

Minor criteria

1. Basilar crackles on lung examination
2. Decreased diffusion capacity, and
3. Arterial hypoxemia at rest or with exercise

Differential diagnosis is important from few other syndromes, which may present with similar clinical manifestations. For example, inhalation of organic dusts may result in organic dust toxic syndrome (ODTS), which unlike HP, may occur in any individual without any prior sensitization. The condition may be noted in a large number of people exposed to a great amount of organic dust. Patients suffering from this experience fever, dyspnea and nonproductive cough. There is leucocytosis and BAL fluid reveals presence of neutrophils. The condition is not associated with any characteristic radiologic abnormalities. It does not lead to any permanent lung damage.[39]

Exposure to the etiological agents of humidifier lung may also result in a non-HP syndrome, the humidifier-fever. Again, the sensitization is not required. The condition exhibits with fever, chills, myalgias, arthralgias, headache, malaise, cough and dyspnea. These features are noted 4 to 12 hours following exposure. There is leucocytosis. The clinical manifestations recede in 12 to 24 hours after cessation of exposure.

Chronic HP exhibits with features of Idiopathic Pulmonary Fibrosis (IPF). The hypersensitivity pneumonitis is distinguished from IPF on the basis of a detailed history of occupational and vocational history. One should make every effort to establish a link between a particular exposure either at work or at home and earlier episodes of similar manifestations. Further, it should be possible to demonstrate the presence of serum antibody to an agent known to cause hypersensitivity pneumonitis. IPF, on the other hand, is a progressive disorder without any recognizable exposure or antibody response.

Proof of repetitive symptoms, laboratory and radiological abnormalities associated with exposure to a particular environment helps in arriving at a diagnosis of hypersensitivity pneumonitis. It has to be confirmed by the demonstration of abnormal white cell count, abnormal chest radiograph or HRCT scan, decreased diffusing capacity or arterial hypoxemia. Lung biopsy confirms the diagnosis.

PROGNOSIS

Hypersensitivity pneumonitis pursues a variable course. If the condition is recognized early, the recovery is generally expected. Generally, the manifestations of acute HP regress after a short interval following stoppage of exposure. Pulmonary functions return to normality within 2 weeks after an acute attack. When the acute attacks are recurrent, the symptoms may persist and lead to progressive lung impairment. The subacute or chronic HP exhibits insidious onset of symptoms. Often the conditions are recognized later in the course of illness, it makes the prognosis unfavorable. The condition may exhibit features of emphysema in later stages of farmer's lung disease or fibrosis in bird breeder's disease.[40,41] Continued exposure to an inciting antigen leads to an accelerated decline in lung functions.

PREVENTION

Hypersensitivity pneumonitis is essentially preventable by avoiding the inciting antigens. The acute episodes are self-terminating and subside if the patient is removed from the antigen-containing environment. Those who continue to be exposed to the antigen for a prolonged period of time develop symptoms insidiously and exhibit a progressive functional deterioration with the development of structural changes within the lung.

The drying of hay minimizing its moisture content and pretreatment of sugarcane bagasse reduces the occurrence of farmer's lung and bagassosis, respectively. The avoidance of birds is essential in bird fancier's lung disease.

MANAGEMENT

Early diagnosis of HP is essential as it facilitates the avoidance of suspected antigen. Avoidance of the offending antigen forms the cornerstone of therapy. It may necessitate change in occupation and hobbies to enable complete avoidance of antigens. There is a need to bring about change in the work environment and improve ventilation so as to minimize exposure. Efforts are made to minimize growth of an offending organism in the environment and removal of the contaminated source. The workers should wear properly fitted masks during exposure.

Persons suffering from acute manifestations respond to administration of corticosteroids. However, the utility of corticosteroids in chronic condition is not proven. A short course of corticosteroids hastens recovery and further stoppage of exposure to dust in the early stages revert the lung to the original condition. Prednisolone, 40 to 60 mg daily is given to achieve an improvement. It is continued for two or more weeks or until there is resolution of clinical and radiological abnormalities. The dose is then gradually tapered after demonstrating objective improvement in pulmonary functions. Bed rest and supplemental oxygen inhalation are advocated. When irreversible fibrosis has developed as in budgerigar's disease, steroids are not helpful and the withdrawal from contact with budgerigars shows limited improvement. The removal of contaminated air-conditioner or humidifier is essential to prevent humidifier pneumonitis.

Toxic Inhalations and Thermal Lung Injuries

VK Vijayan, N Goel, R Caroli

INTRODUCTION

The airways and lung parenchyma are in constant contact with the external environment and thus are especially vulnerable to damage by toxic or irritant substances released in the atmosphere. A person can be exposed to such toxic materials as a result of industrial disasters,[1,2] occupational exposures,[3,4] recreational mishap,[5] natural catastrophe,[6] chemical warfare[7] and acts of terrorism.[8, 9] The inhalation of smoke results in a series of pathophysiological events involving the respiratory and circulatory systems. Upper airway injury is mainly due to heat damage. The lesions of the tracheobronchial and parenchymal areas are mostly related to the chemicals present in the inhalants. Lung damage may take place even after a single exposure to an irritant gas, fume or vapor. Within seconds of exposure to an inhaled toxin, pathological events occur that may cause immediate distress, systemic illness lasting days or even lead to the development of chronic lung disease. Clinicians need to be aware of the mechanisms, natural history, treatment and prevention of inhalation injury due to different agents so that they can manage individual patient accordingly.[10,11] Pulmonary responses based on consequences of exposure are listed in Table 113.1.

DETERMINANTS OF INHALATIONAL LUNG INJURY

A variety of factors determine the pathological changes of a toxic inhalation, viz. the size of inhaled particles, solubility of the inhaled substance in water, concentration of the inhalant in ambient air, duration of exposure, presence or absence of ventilation and a variety of host factors (age, smoking status, comorbid diseases, use of respiratory protection and perhaps even genetic susceptibility).[12,13] The size of aerosolized particles is of critical importance in inhaled toxin pathogenesis, as it determines the nature and site of injury. In general, larger aerosolized particles are more likely to deposit on the nasopharynx via impaction and may not gain access to the lower airways, while smaller particles are able to penetrate smaller airways and effect toxicity at the level of the alveolus. Particles of over 10 μm are lodged in the upper respiratory tract, while those less than 0.5 μm are usually exhaled. Thus, particles between these sizes are inhaled into the bronchi and if less than 3 μm, into the alveoli, causing diffuse damage. Water solubility plays a key role in determining where inhaled gases/particles get deposited in the respiratory tract.[11] Highly soluble agents (e.g. hydrochloric acid, sulfur dioxide, ammonia and aldehydes) have an early effect (within minutes of exposure) and cause acute irritant injury to the mucous membranes. This results in damage and related symptoms of the conjunctiva, nose and upper airway, but spare the lower respiratory tract. Those with low solubility (e.g. nitrogen dioxide, nitrous oxide, phosgene and ozone) cause no symptoms in upper airway and predominantly penetrate into the lower airways. Hence, they cause delayed onset irritant effects in bronchi, terminal bronchioles and alveoli. Because of the delayed effects and symptoms, exposure is often not noted early by the subject and exposure can thus be prolonged and more damaging.[14]

TABLE 113.1: Consequences of exposure

S.No.	Diseases	Common Agents
1.	Upper respiratory tract diseases	
	a. Rhinitis and laryngitis	a. Dust from flour, latex, pollens, ammonia, SO_2, ETS, hypochlorous acid
	b. Rhinorrhea	b. Cold air, carbaryl, malathion, parathion
	c. Ulceration and perforation of nasal septum	c. Arsenic, copper dusts, chromic acid and chromates
2.	Airway diseases	
	a. Asthma	a. Acid anhydrides, aldehydes, chlorine, dust from flour, latex, pollens, isocyanates
	b. Bronchitis	b. SO_2, rock and mineral dusts
	c. Bronchiolitis	c. Acetaldehyde, ammonia, chlorine
3.	Interstitial diseases	
	a. Pulmonary fibrosis	a. Asbestos, crystalline silica, talc
	b. Alveolar proteinosis	b. Fine crystalline silica dust
	c. Lipoid pneumonia	c. Oily metal working fluids
	d. Hypersensitivity pneumonitis	d. Fungi, thermophilic bacteria
	e. Granulomatous diseases	e. Beryllium
	f. Inhalation fever	f. Ameba, fungi, cotton dust, freshly generated zinc fumes
4.	Chronic obstructive pulmonary disease	Coal dust, cotton dust, cadmium, crystalline silica
5.	Lung cancer	Asbestos, arsenic, mustard gas, radon progeny, cadmium, crystalline silica

SO_2: Sulfur dioxide, ETS: Environmental tobacco smoke

CLINICAL PRESENTATIONS OF INHALATIONAL INJURY

Upper Airways

The effects of acute inhalation injury on the upper airways range from simple, transient irritation to airway compromise.[11-15] The initial nasal mucosal response to inhaled toxins is typically sudden and short-lived compared with the distal airways and hence, chronic pathology is unusual. Characteristic tissue injury ranges from slight edema of the nasopharynx and larynx to epithelial ulceration and frank hemorrhage. Once the airway epithelium is compromised, it fails to function as a protective barrier against the environment. Underlying inflammatory cells, nerves, muscles and blood vessels become exposed, which makes it sensitive to further lower concentrations of irritants. Substances that are inhaled into the nose are perceived as olfactory stimuli (olfactory nerve) or irritant stimuli (trigeminal, glossopharyngeal and vagus nerves).

Patients with the acute exposure of irritant substances to the upper airways present typically with complaints of burning sensations of the nasal passages and throat, copious sputum production, coughing and sneezing. Other symptoms include burning of the eyes, profuse lacrimation, headache and dizziness. Besides these, exposed persons can present with life-threatening airway obstruction due to reflex bronchoconstriction, laryngospasm/glottic closure, mucosal edema, increased secretions and sloughed epithelial cells. The larynx, which has the smallest cross-sectional area in the respiratory tract, causes a narrowing of air stream where air velocity increases eddies form and particulate matter gets deposited, which further predispose to laryngospasm. Along with the upper airways, epithelial injury can occur in the conducting airways by acute toxic inhalation which exposes submucosa to dangerous effects of toxins. Mild irritant effects include tracheitis and bronchitis. Irritation and inflammation can aggravate underlying airways disease, such as chronic obstructive pulmonary disease (COPD) or bronchial asthma. The resulting edema, inflammation and bronchoconstriction may be life-threatening. The airways are also vulnerable to infections and other environmental pollutants due to the loss of the epithelial barrier. The smooth muscle of the airways can be hyperresponsive following the irritant exposure. The injury to the conducting airways may manifest as intrathoracic airflow obstruction, hours after the initial insult and patient may present with dyspnea or chest tightness and wheezing. Chronic effects of irritant injury to the conducting airways include chronic bronchitis and tracheitis. If individuals have a pre-existing airway disease, the irritant exposure may cause more severe disease.[16]

Reactive Airways Dysfunction Syndrome (RADS)

An acute, excessive exposure to a number of chemicals, regardless of whether or not the agent has the potential to induce sensitization, can result in RADS.[17-19] The diagnostic criteria for RADS are given in Table 113.2.[20] The interval between the time of the exposure and the appearance of asthma symptoms in RADS is very short, often just a few hours. Subjects develop asthma-like symptoms within 24 hours after the single exposure. The agents that cause RADS include high-level exposure to an irritant gas, vapor or fume-like uranium hexafluoride gas, floor sealant, spray paint containing significant concentrations of ammonia, heated acid, 35% hydrazine, fumigating fog, metal coating remover and smoke. The exposure induces persistent nonspecific bronchial hyperresponsiveness. Bronchial biopsy demonstrates bronchial epithelial cell injury and bronchial wall inflammation with lymphocytes and plasma cells, but without eosinophils. At the time of medical examination, all subjects show a positive methacholine challenge test with PC20 of 8 mg/mL. There is a lack of any specific underlying host susceptibility (e.g. cigarette smoking, pre-existing lung disease or atopy). Chest radiographs may be normal and pulmonary function tests are normal or show mild airflow limitation. Subsequently, most persons with RADS require antiasthma medications that they were not taking before the exposure.

TABLE 113.2: Diagnostic criteria for RADS

1. Absence of pre-existing respiratory disorder, asthma symptoms or a history of asthma in remission
2. Exclusion of conditions that may mimic asthma
3. Exposure to an irritant vapor, gas, fumes or smoke in very high concentrations
4. Onset of asthma symptoms within minutes to hours and <24 hours after a single exposure or accident
5. Positive methacholine challenge test
6. Pulmonary function test to document airway obstruction (may or may not be present)
7. Exclusion of another pulmonary disorder

Irritant-induced Asthma

Patients not meeting the criteria of RADS are categorized as having irritant-induced asthma.[21] These patients usually have history of repeated episodes of less massive exposures and develop symptoms after a lag of several days.[20] Repeated exposures to irritants lasting days or weeks are required before the development of asthma.

Bronchiolitis Obliterans

Bronchiolitis obliterans is a disease where there is damage to the epithelium of the small conducting airways and frequently of the adjacent alveolar tissue that progresses to inflammation; the clinical consequence of this injury is irreversible airway obstruction. Although there are several patterns of primary bronchiolitis, constrictive bronchiolitis (also called obliterative bronchiolitis or bronchiolitis obliterans) is the most pertinent in inhalation injuries. Constrictive bronchiolitis often accompanies connective tissue disorders. Other causes are infections, chronic hypersensitivity pneumonitis, drugs and organ transplantations. Inhalational bronchiolitis obliterans evolves after inhaling an irritant gas, fume, vapor (and rarely dust), such as nitrogen dioxide, sulfur dioxide, ammonia, chlorine, phosgene, hot gases or fly ash. There were sporadic cases of bronchiolitis obliterans among nylon-flock workers, workers who sprayed prints onto textiles with polyamide-amine dyes, battery workers exposed to thionyl chloride fumes and workers in the food-flavoring industry.[21-24]

There is a classic three-phase pattern of response to gaseous exposures, such as nitrogen dioxide. Within first-four to six hours, upper airway symptoms predominate if the exposure is due to a more water soluble gas, such as sulfur dioxide; not as much upper airway symptoms take place when the gas was less soluble, such as with nitrogen dioxide. The exposure also causes diffuse alveolar damage that leads to a second phase characterized by the acute respiratory distress syndrome (ARDS), which develops within the first 24 hours. After resolution of ARDS, there is a third phase (perhaps several weeks after the exposure); where there are 7 to 10 days of minimal respiratory symptoms and then a gradual progression of shortness of breath. In most cases, constrictive bronchiolitis is progressive and poorly responsive to corticosteroids. Progressive airflow limitation may result in respiratory failure and death.[25-27]

Chest radiography may be normal or show only nonspecific abnormalities. There may be variable amounts of hyperinflation, peripheral attenuation of the vascular markings and sometimes, nodular or reticulonodular opacities. If serial radiographs are available, progressive hyperinflation can be appreciated. There may be changes consistent with bronchial wall thickening and bronchiectasis. A more sensitive diagnostic tool is high-resolution computed tomography (CT) scans, which typically show diffuse mosaic areas of decreased attenuation and vascularity, evidence of air-trapping (accentuated on expiratory views) and peripheral cylindrical bronchiectasis. Pathologically, constrictive bronchiolitis is characterized by peribronchiolar fibrosis with scarring of the bronchiolar lumen. The fibrosing inflammatory process surrounds rather than fills the lumen, resulting in extrinsic compression and obliteration of the airway. There are subtle and often patchy areas of fibrosis that may be missed if lesions are inadequately sampled. Therefore, transbronchial lung biopsy is a relatively insensitive diagnostic tool and usually a surgical lung biopsy is necessary.

Acute Respiratory Distress Syndrome

Although all toxic inhalants are capable of producing distal airway disease at extreme concentrations and durations, the gases most likely to do so are those with low water solubility, such as phosgene and nitrogen dioxide, which bypass reflex bronchoconstriction and absorption by upper airway mucosa.[27] The initial pathological events in distal airways are caused by the cellular toxicity of the inhaled agent and its derivatives, which compromise the impermeability of the alveolar-capillary interface. Some of this cytotoxicity may be derived indirectly from reactive oxygen species released from activated inflammatory cells. In the absence of an intact alveolar-capillary interface, profound pulmonary edema may develop that impairs gas exchange and can prove fatal. The severity of this pulmonary edema, which typically presents after a latent period of several hours following the initial insult, is likely dose related. This process may cause no more than slight dyspnea and cough with a mild alveolar infiltrate or may progress via diffuse alveolar damage to ARDS.

SPECIFIC INHALED TOXINS

Bhopal Methyl Isocyanate Disaster

The world's worst chemical industrial disaster occurred at Bhopal (India) on the night of 2nd to 3rd December, 1984. The leakage of the gases took place at a pesticide plant from a buried stainless steel tank in which 42 tons of Methyl Isocyanate (MIC) had been stored. This episode resulted in the immediate death of approximately 2,500 people and the exposure of over 3,50,000 people in the Bhopal City, comprising of over 8,00,000 inhabitants.[28-30] The main symptoms on the initial day were breathlessness (99%), cough (95%), throat irritation or choking (46%), chest pain (25%) and hemolysis (12%).[31] Many patients had features suggestive of pulmonary edema with froth coming out of the mouth immediately after the exposure (Fig. 113.1). Radiological studies done 72 hours after the leakage mainly showed alveolar and interstitial edema.[32] The predominant type of ventilatory defect, one to three months after exposure was combined obstruction and restriction.[33,34] Open lung biopsies, six to eight months after the exposure showed thickened alveolar walls, macrophages in the alveoli, some interstitial fibrosis and destructive changes in the terminal bronchioles with exudates in the lumen, a picture, which was suggestive of bronchiolitis obliterans.[28]

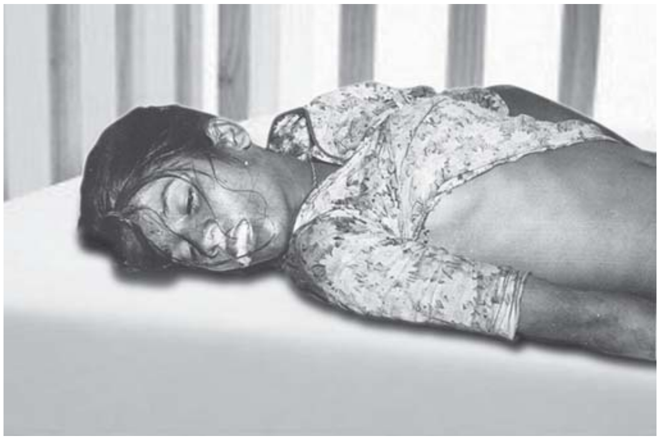

Fig. 113.1: One of the victims died due to MIC exposure with froth coming out of the mouth and nose

Bronchoalveolar lavage (BAL) studies of 1 to 2½ years after exposure to the gas had shown an increase in cellularity in the lower respiratory tract (alveolitis) of the severely exposed subjects.[35] The increase in cellularity in severely exposed nonsmokers was due to the abnormal accumulation of macrophages suggesting a subclinical alveolitis. Bronchoalveolar lavage studies repeated in these subjects 1.4 ± 0.6 years after the first lavage had revealed that the lower respiratory tract inflammation had progressed from initial macrophage alveolitis to macrophage-neutrophilic alveolitis.[36] Bronchoalveolar lavage studies in a new group of subjects 5.1 ± 1.0 years after exposure had confirmed chronic inflammation of the lower respiratory tract as evidenced by macrophage-neutrophilic alveolitis in these subjects as well.

Clinical, radiographic and pulmonary function abnormalities were found to persist in these subjects.

Fibronectin (FN) levels in BAL fluid had been found to be elevated in 29.3% of subjects.[36] Total lung inflammatory cells and absolute numbers of macrophages and lymphocytes in BAL fluid increased as the severity of exposure increased. There was a significant increase in lung eosinophils as time passed.[37] Forced Expiratory Volume in One Second/Forced Vital Capacity% (FEV_1/FVC%) was significantly lower as severity of exposure increased. Bronchoalveolar lavage neutrophils, both percentage and absolute numbers showed significant negative correlation with FEV_1% predicted. Neutrophil percentage was negatively correlated with FEV_1/FVC%. Radiographic abnormalities were associated with decline in FEV_1% predicted.[37]

Clinical, radiological and pulmonary function changes were noticed 4.7 ± 1.4 years (range three to seven years) after exposure. Obstructive ventilatory defect was seen in 33% and restrictive defect in 16% of the individuals. Pulmonary function abnormalities were predominantly seen in subjects severely exposed to the gas.[38] Computed tomographic evidence of pulmonary fibrosis was also described in a patient with toxic gas exposure.[39] Small airways obstruction was found to persist among survivors of the disaster even 10 years following the gas leak.[40] These studies suggest that the pulmonary function abnormalities persisted in subjects exposed to the gas and that irreversible changes in pulmonary function occur in subjects who had severe exposure.[37] Thus, a single massive exposure to the gas in Bhopal has resulted in residual lung damage especially obstructive airways disease.

Nitrogen Oxides (NO_x)

The main sources of nitrogen oxides are from automobile engines, combustion of coal and petroleum and smoking of cigarette. Mining, acetylene welding and manufacture of explosives are other sources from industrial settings. Inhalation of concentrated nitrogen dioxide gas released from decomposing nitrogenous material in silos leads to "silo-fillers" disease in farmers. Nitrogen oxides can occur as nitrogen dioxide, nitrous oxide, nitrogen peroxide and other nitrous oxides. Nitrogen dioxide is a red/brown pungent gas.

The initial effects of nitrogen dioxide exposure are relatively benign but at very high concentrations may result in cough, fatigue and occasionally nausea.[41-44] With high-intensity exposure, patients may experience headache and chest tightness, although these symptoms tend to resolve promptly. Nitrogen dioxide is less irritating to mucosal surfaces than other toxic inhalants. Symptoms typically abate initially, however, an intense pulmonary edema consistent with ARDS develops after a few hours due to increased capillary permeability following extensive damage to vascular and airway epithelium. Patients who survive are at an increased risk for the development of bronchiolitis obliterans and bronchiolitis obliterans organizing pneumonia, one to four weeks following exposure.

Sulfur Dioxide (SO_2)

Sulfur dioxide is a byproduct of the combustion of fossil fuels, i.e. coal and petroleum. It is often used as a preservative in alcoholic beverages and fruit. Ore smelting, sugar refining and the bleaching of wool and wood pulp, volcanic eruptions are other important sources. Sulfur dioxide is a major component of air pollution smog. Sulfur dioxide is a heavy, colorless and highly water-soluble gas that has the distinct, pungent odor of burnt matches. It settles in the ground due to its high density and dissipates slowly from the sites of release. Sulfur dioxide reacts with the water present on mucous membrane to form sulfuric acid, which causes local tissue destruction. Sulfuric acid further dissociates into hydrogen ions, sulfite and bisulfite, which can then react with oxygen to produce reactive oxygen species; ensuing lipid peroxidation may be a contributing mechanism of injury to immediate tissues and elsewhere.[45-47]

Symptoms of SO_2 inhalation include dyspnea, burning of the nose and throat, rhinorrhea, cough and airway obstruction. Proximal airway injury is characterized by acute denudation of the airway mucosa without inflammatory cell infiltrates. When lower airways are exposed, alveoli are filled with fluid due to noncardiogenic pulmonary edema and a clinical picture consistent with ARDS develops. Extremely high-intensity acute exposures can lead within minutes to death from respiratory failure. Reactive airways dysfunction syndrome and bronchitis can also occur. Sometimes, there may be initial recovery followed several weeks later by the onset of irreversible airflow obstruction due to bronchiolitis obliterans.

Phosgene ($COCl_2$)

Phosgene is released due to the production of pesticides, polyurethane resin, toluene di-isocyanate, pharmaceutical products and dyes. It can also be released accidentally via the heat decomposition of various solvents, paint removers, dry cleaning fluids and methylene chloride. Individuals may not be aware of exposure to phosgene because of its properties of being colorless, lacking a strong odor (in high concentrations it is reported to smell like moldy hay, new-mown hay or green corn) and not irritating to the nasal and oral mucosa. It was used as chemical warfare agent in World War I because it showed the above mentioned properties.

Phosgene reacts with water to form hydrochloric acid and carbon dioxide, resulting in local epithelial necrosis. Its lack of irritability in the upper airways ensures the passage of the gas to the alveoli inflicting significant damage in alveoli.[48,49] Phosgene also causes tissue damage by rapidly acetylating the amino, hydroxyl and sulfhydryl groups of proteins, resulting in protein denaturation and structural compromise of cell membranes, leading to a breakdown of the blood-air interface. Lipid peroxidation has also been shown to occur and antioxidant therapy has been shown to attenuate its effects in animal models.

Victims may present with chest tightness, wheezing or cough or sometimes may be asymptomatic. Post-exposure, there may be a variable latent period of up to 48 hours before the onset of symptoms of pulmonary edema/acute lung injury. The duration of this latent period is thought to be inversely proportional to both the severity of exposure and the ensuing severity of disease. The patient experiences dyspnea, cough and respiratory distress, and rales and cyanosis may also be present. Dyspnea or radiographic evidence of pulmonary edema within four hours after exposure indicates a worse prognosis and warrants treatment in an intensive care unit. Although, survival for patients with acute phosgene exposure is good, numerous long-term sequelae have been reported, including prolonged exertional dyspnea, chronic bronchitis and emphysema.

Ozone (O_3)

Ozone is highly toxic to respiratory tract. It is an important oxidant pollutant in smog. It is widely used in water purification systems and is a byproduct of electric currents passing through air, as in welding and corona wires of photocopying machines. It is also used for the bleaching of fabrics and the manufacture of plastics. Ozone is a colorless, odorless gas having low water solubility. This leads to a lack of early irritating warning effects and an increased probability of damage to the conducting airways and lower respiratory tract. Ozone exposure results in the formation of free oxygen radicals and lipid peroxidation, which causes oxidative cellular damage. Severe exposures can cause dyspnea, cyanosis and pulmonary edema.[50,51] At higher doses, ozone exposure has been found to be associated with the development of RADS.

Ammonia (NH_3)

Anhydrous ammonia (NH_3) is a colorless gas with a strong odor. It is generally stored and transported under pressure as liquid. It is used as a household cleaner and in industries as a chemical coolant for refrigeration, as fertilizer, as fixative in photocopiers and in the manufacture of polymers and explosives. Small amounts are naturally present in the atmosphere as products of the putrefaction of vegetables and animal proteins. Most inhalation exposures are the result of accidental releases, including tank leaks and transportation mishaps, as well as from exposures that occur in the industrial workplace. Accidental releases of anhydrous ammonia caused by explosions or other accidents can lead to severe chemical inhalation injury as well as dermal and conjunctival burns because of the strong alkaline properties of ammonium hydroxide and hydroxyl ions formed in an exothermic reaction when ammonia reacts with water on the surface of mucous membranes.

Anhydrous ammonia and ammonium hydroxide have an affinity for mucous membranes that leads to liquefactive necrosis and full thickness tissue destruction. The resulting injury, typical of alkali burns, penetrates deeply. The initial injury to the mucosa of the oropharynx can cause edema, hemorrhage, sloughing of tissue and increased secretions that can bring about fatal upper airway obstruction. Ammonia is directly caustic to airways at concentrations of 1000 ppm and higher. Although concentrated at the proximal airways, the effects of ammonia have been observed at all levels of the respiratory tract. The penetration of the gas to the smaller airways and alveoli is a function of its concentration and the duration of exposure.

Inhalation injury with ammonia can lead to pharyngitis, laryngitis/tracheobronchitis, hemoptysis, pulmonary edema, bronchiolitis and bronchopneumonia. Chronic sequelae include bronchiectasis, RADS and COPD.[52-54] Occurrence of interstitial lung disease has been seen in survivors following a single exposure to ammonia. A biphasic pattern of pulmonary response to ammonia inhalation has been reported, characterized by initial, acute pneumonitis that may clear over the next two to three days, followed in some individuals by the gradual development of airway obstruction and respiratory failure. There may be a relationship between the bacterial superinfection after exposure and the ensuing development of bronchiectasis. The most common causes of death are laryngeal edema and obstruction, noncardiogenic pulmonary edema and extensive pneumonic complications.

Chlorine, Chloramines and Hydrochloric Acid

The first reports of chlorine toxicity were during its use as an agent of chemical warfare in World War I. Exposures to chlorine occurs in industrial settings where chlorine is used in the manufacture of paper, cloth, antiseptics and other products. Household exposure has been observed due to the liberation of chloramines and other toxic chlorine derivatives from the reaction of chlorine-containing products (e.g. hypochlorite bleach) with ammonia or products containing hydrochloric or phosphoric acids. Numerous exposures to chlorine gas have been reported to occur near swimming pools where chlorine-releasing agents (e.g. calcium hypochlorite and chlorinated isocyanuric acids) are used in water purification.

Chlorine gas is a greenish-yellow gas that has strong irritant and odor. A slight mucous membrane irritation of eyes, nose and throat occurs at concentrations of 1 to 3 ppm and noticeable irritation occurs at brief exposure of 3 to 6 ppm. The pathogenicity of chlorine gas occurs directly from elemental chlorine's effects on the respiratory tract and indirectly from its reaction with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). Hyrdrochloric acid and HOCl possess considerable water solubility and are responsible for the tissue damage of the upper airways and ocular conjunctivae. Irritation to trigeminal nerve endings caused by these compounds can cause a reflex bronchoconstriction that may contribute to compromise in airway diameter. In addition to cause the tissue coagulation typical of acid exposures, these compounds ionize and enter cells, where they may form reactive oxygen species. Although, lower respiratory tract irritation has been reported following high-level of exposure, only less than 5% of inhaled chlorine gas penetrates beyond the upper airways. Fatal dosages from chlorine inhalation have ranged from 50 to 2000 ppm.

The immediate clinical manifestations of acute chlorine exposure are typical of its irritants effects, viz. rhinitis, cough, dyspnea, wheezing and chest tightness along with conjunctivitis and skin irritation. Lower respiratory tract may be affected in the form of pneumonitis and pulmonary edema. Acute respiratory symptoms are more prevalent and severe among patients who already have chronic respiratory disease. Respiratory sequelae of chlorine gas exposure have been described since the years following the use of the gases in World War I. Long-term pulmonary sequelae have included both restrictive and obstructive processes, frequently resolving to normal function within a month and almost always before two years following exposure.[55-58] Reactive airways dysfunction syndrome may be infrequent sequelae of high-level exposures to chlorine.

Cadmium

Cadmium is used in nickel cadmium batteries and is also found in alkaline accumulators, electroplating, bearings, solders and as a barrier around nuclear fission generators. It is present in many metal ores and cadmium-containing pigments are used in paints, artists' colors, rubber, plastics, printing inks, wallpaper, leather, glass and enamels. Most inhalations occur to workers who are involved with soldering, brazing, smelting and refining. The mechanisms involved with the acute lung injury due to cadmium inhalation are not well defined. Postmortem examinations of individuals who died after accidental acute inhalation exposure have revealed tracheobronchitis, consolidated lungs, denuded bronchial epithelium, intra-alveolar hemorrhage and the presence of macrophages in the alveolar spaces. It is known that cadmium inhibits the synthesis of plasma alpha 1-antitrypsin, which may explain the correlation between cadmium exposure and the later development of emphysema.[59]

When cadmium-containing materials are heated, cadmium vapors and cadmium oxide fumes are released. These can produce a systemic flu-like syndrome, which resembles metal fume fever. They are asymptomatic for several hours before developing fever, malaise and myalgias. These constitutional symptoms are often accompanied by or shortly followed by respiratory distress including cough, chest tightness and dyspnea. Cadmium exposure can also lead to a severe pneumonitis which can progress to ARDS, pulmonary hemorrhage and eventual death from respiratory failure. Cadmium may be detected in the urine.[60]

Mercury

Mercury is used in mining operations, dental amalgams, jewellery production and light bulb manufacturing. It is present in the form of environmental hazard as a component of thermometers, sphygmomanometers and other specialized equipment. Like phosgene and cadmium, mercury vapor has little or no immediate upper airway or mucosal surface irritant effects. As a result, exposed individuals may inadvertently remain in an area where the harmful vapors are present. The toxicity of mercury vapors within the lung is thought to be due in part to the irritant effects of oxidized mercurous and mercuric ions and the disruption of enzyme systems containing sulfhydryl groups. Mercury coagulates protein, blocks cellular metabolism of carbohydrates at the pyruvic oxidase level and as a result produces metabolic acidosis. Lung pathology following acute exposure reveals pulmonary edema, capillary damage and the desquamation and proliferation of airway epithelium followed by an obliteration of airspaces.[61, 62]

Inhalation of mercury vapors causes cough, dyspnea and respiratory distress developing over a 24-hour period. These initial symptoms may be accompanied by fever, nausea, vomiting, diarrhea and a metallic taste in the mouth, similar to what is often experienced by individuals with metal fume fever. In fact, mercury vapor inhalation can be mistaken for metal fume fever or influenza. However, symptoms of mercury vapor inhalation do not spontaneously resolve as with metal fume fever. Like cadmium, the pneumonitis due to mercury exposure may progress to ARDS and respiratory failure, sometimes accompanied by pneumothorax. Death has been preceded in several reports by tension pneumothorax. Inhaled mercury vapor is absorbed rapidly into the blood, where it can cause systemic toxicity in the form of renal, hepatic and nervous system pathology. Patients surviving the acute injury typically experience resolution of their symptoms within one week, but have also progressed to develop interstitial fibrosis. Mortality due to exposure may be increased in children.

Zinc Chloride

Zinc chloride is formed when zinc oxide is ignited with hexachloroethane. The smoke obscures vision, resulting in directional disorientation and the individual is unable to quickly escape the area of exposure. Zinc chloride ($ZnCl_2$, or hexite) is a major ingredient of smoke bombs/smoke-generating devices. Zinc chloride is in particulate form with an average particle size of 0.1 µm and hence, it penetrates to the lower respiratory tract. After depositing on the airway and alveolar surfaces, zinc chloride reacts with water to form hydrochloric acid and zinc oxychloride. This directly causes irritation of exposed mucosal surfaces and is the probable mechanism behind the diffuse lung injury observed on exposure. Zinc chloride inhalation is followed by tracheobronchitis and pneumonitis. Patients experience cough, dyspnea and chest tightness followed by a period of relative stabilization before progressing to ARDS.[63,64] Chest imaging may be normal initially, but can reveal pleural effusions, pneumomediastinum and bilateral infiltrates consistent with pneumonitis. Prominence of ground glass opacities observed on high-resolution CT imaging may be predictive of severity of exposure and length of hospital stay. Urine zinc levels are useful for confirming the diagnosis of zinc inhalation toxicity.

Tear Gas

"Tear gas" is the name, collectively given to the disabling chemical irritants of which there are more than a dozen chemicals, but the five commonly used chemicals are: 2-chlorobenzylidene-malonitrile (CS, Tear gas), 1-chloroacetophenone (CN, mace), dibenz-1,4-oxazepine (CR, Fire gas), oleoresin capsicum (OC, pepper) and Pelargonic Acid Vanillylamide (PAVA).[65] All these agents are used by military and law enforcement agencies to control crowds and individuals, making use of their intense and immediate irritant effects on mucous membranes and lacrimal glands. The tear gas affects the exposed cutaneous and mucous membrane surfaces.[66] Exposure to any of them results in immediate rhinorrhea, mucositis, chemical conjunctivitis and profuse lacrimation. Immediate pulmonary effects include an intense burning sensation in the upper airways, reflex airway constriction, chest tightness, dyspnea and cough.[67,68] Exposure may also provoke nausea, headache and photophobia. Severity of response depends on the concentration of the agent used, duration of exposure and presence or absence of ventilation and protective breathing apparatus. The effects of tear gas are predominantly due to its upper airway irritant effects and thus lower airway injury and parenchymal disease is rarely observed. Some exposed persons may develop severe pulmonary disease in form of pneumonitis, pulmonary edema and reactive airways dysfunction syndrome. In asthmatic individuals, it may precipitate acute bronchospasm.

World Trade Center Disaster

The World Trade Center (WTC) in New York was struck by two commercial jets on 11th September, 2001, leading to the collapse of three skyscrapers. As a result, 2,751 persons, including 373 firefighters from the New York City Fire Department (FDNY) died. The WTC collapse has produced a massive exposure to respirable particulates, with the larger-size fractions having a pH ranging from 9 to 11 leading to an alkaline burn of the mucosal surfaces.[69] The survivors, both rescue workers and bystanders, were exposed to respirable particulates and combustion byproducts.[67] Induced sputum from FDNY workers had shown high levels of particulates and evidence of continuing inflammation 10 months after exposure to WTC dust.[70] Intense short-term exposure to materials generated during the collapse has been shown to be associated with bronchial responsiveness and development of asthma.[71] Respiratory symptoms, either new or increased in severity have been described in FDNY rescue workers, other exposed workers and residents.[72] During the first year post-September, 2001, there was a parallel decline in both FEV_1 and FVC resulting in a low FVC and normal FEV_1/FVC in the FDNY rescue workers and in non-FDNY rescue/recovery workers raising the possibility of interstitial lung disease in exposed subjects.[71,73] However, pulmonary function evaluation during the first seven years postexposure in FDNY rescue workers had shown that airways obstruction was the predominant physiologic abnormality.[74]

SYSTEMIC ILLNESSES FROM INHALED TOXINS

Systemic flu-like illness lasting less than two days has been observed in patients exposed to organic dusts and fumes of heated metals and fluorocarbons. These are known as inhalational fevers and are of three types, viz. metal fume fever, polymer fume fever and organic dust toxic syndrome (ODTS). The course of the disease is self-limited and appears to be cytokine mediated.

Metal Fume Fever

Metal fume fever (MFF) is a self-limiting inhalation fever attributed to a number of metal oxide fumes. The history is characterized by fever, headache, myalgia, fatigue and dyspnea. Other features include cough, thirst, a metallic taste, salivation and a neutrophilic leukocytosis. Metal fume fever is an important occupational-related illness classically associated with zinc oxide fume exposure from welding galvanized steel or brass.[75,76] It is also seen in association with high temperature zinc coating processes and metal pouring in brass foundries. Magnesium and copper oxide fumes are more rarely the causative agents. Metal fume fever has been known by a number of other names: Brazier's disease, smelter shakes, brass chills, zinc chills, welder's ague, copper fever, foundry fever and Monday morning fever. Radiography may demonstrate bilateral diffuse infiltrative pulmonary lesions. Pulmonary function tests demonstrate a significant reduction in vital capacity, transfer factor and arterial oxygen partial pressure. Urine and plasma metal levels may be increased. Onset is typically rapid, occurring between three and ten hours after exposure. Spontaneous recovery occurs within 24 hours. No long-term complications are known.

Specific fumes that have been blamed include those of beryllium, cadmium, copper, magnesium, nickel, silver and zinc. Welders are at the highest risk for metal fume fever contraction, although it has been reported in other metal working occupations, including soldering, brazing, cutting, metalizing, forging, melting and casting. Episodes of varying severity of metal fume fever may be experienced by between 20% and 35% of all welders. Repeated exposure may lead to tachyphylaxis. The name "Monday morning fever" refers to the recurrence of acute disease on return to exposure following a short period of absence. Metal fume fever is generally thought to have no long-term sequelae. An association between it and the later development of occupational asthma has been observed.[77,78] The pathogenesis of metal fume fever appears to involve an increase in proinflammatory cytokine activity in the lung; increased BAL fluid concentrations of tumor necrosis factor (TNF), interleukin-6 (IL-6) and interleukin-8 (IL-8) have been reported in subjects exposed to zinc oxide fumes, probably produced by pulmonary macrophages.[79] Of the numerous components of metal fumes, it appears to be the soluble transition metal particles, which generate reactive oxygen species and deplete glutathione stores that are responsible for the fumes' cytotoxicity. A proposed mechanism of the observed tolerance to metal fumes involves the increased synthesis of toxic metal-binding protein metallothionein in exposed patients.[80]

Diagnosis is based on clinical suspicion, clinical findings and rapid resolution. Evidence of possible exposure is critical. Treatment is symptomatic. The syndrome needs to be differentiated from serious MFF seen after military smoke exposure, which typically has a biphasic response with severe relapse 24 to 48 hours after initial remission.[81] It should also be differentiated from true chemical pneumonitis after metal fume exposure.

Polymer Fume Fever

Polymer fume fever, a syndrome similar to but less common than metal fume fever. Fluorocarbon polymers are a class of compounds that are commonly used as nonstick coatings on cooking equipment (e.g. polytetrafluoroethylene [PTFE, or Teflon]), but are also used in mold-release sprays, lubricants and fabric or leather treatments. Heating of fluorocarbon polymers produces fumes that contain carbonyl fluoride, perfluorinated alkanes, hydrofluoric acid and carbon dioxide. Polymer fume fever presents similarly to metal fume fever: Initial symptoms include dry throat, rhinitis, chest tightness and conjunctivitis. Constitutional symptoms (fever, chills, and myalgias) typically follow exposure by about four to eight hours and spontaneously resolve within one day.[82,83] As with metal fume fever, a leukocytosis is observed concurrent with the patient's constitutional symptoms. Individuals with pre-existing obstructive lung disease may experience worsening obstruction after recurrent exposures to polymer fumes. Pneumonitis is more frequently observed than with metal fume fever, perhaps due to release of hydrofluoric acid. Tachyphylaxis, a hallmark of metal fume fever, is not observed in polymer fume fever, suggesting that different mechanisms are responsible for the two diseases. As with metal fume fever, the systemic response to particle inhalation appears to be cytokine mediated. Although exposure to pyrolized fluoropolymers occurs in industrial settings where it may be immediately suspected in the context of respiratory complaints, it also occurs in homes.

Organic Dust Toxic Syndrome

Organic dust toxic syndrome (ODTS) is a self-limited syndrome characterized by fever with chills, malaise, myalgia, headache, dyspnea, chest tightness, dry cough and nausea. The syndrome usually begins within hours of an exposure to high concentrations of organic dust. Organic dust is defined as solid particles of 0.1 to 50 microns or larger in diameter that are produced by some mechanical process, such as crushing, grinding, abrading or blasting and suspended in air. The physical and chemical compositions of organic dusts vary and are affected by the dust source, geographic region, temperature, humidity and other factors. Grain dust constituents include fractured grain kernels, trichome particles, insects or insect parts, silica, bacteria and molds and chemical residues.[84-87] Organic dust toxic syndrome typically resolves spontaneously within 48 hours following exposure. Agricultural workers are at the highest risk for contracting ODTS, as it commonly follows exposure to hay or corn silage-containing silos, spoiled animal feed and swine confinement facilities. Other settings of ODTS have included a storehouse containing moldy oranges, a waste-sorting plant, a print-shop in which an air humidifier was colonized with gram-negative bacteria, fungi and amoeba and following exposure to wood chip mulch. The exact mechanisms of toxicity are not known, but endotoxin, fungal spores or mycotoxins are believed to play a role and the mechanism is nonimmunogenic. The amount and duration of exposure are important. Grain dust extracts have been shown to cause alveolar macrophages to produce IL-1, IL-6 and TNF-α, which are endogenous pyrogens. Cytokine expression increases following organic dust exposure. This especially includes proinflammatory cytokines, such as TNF-α and interleukin-6 (IL-6), suggesting a means by which local activation of innate immunity may provoke the observed systemic manifestations. Interleukin-1 is also thought to play a critical role in ODTS development. An intriguing correlation has been observed between patients with celiac disease and the development of ODTS, suggesting that some underlying disorder, perhaps hyperactivity of innate immunity, may increase the patient's susceptibility to both.

Patients with ODTS frequently present with no findings on chest examination, although bibasilar crackles and scattered wheezes may be appreciated. A neutrophil predominant leukocytosis is frequently found and mild hypoxemia and bilateral infiltrates on chest X-ray have been reported. Although, bronchoalveolar lavage may initially reveal the predominance of neutrophils, a lymphocytic response may come to dominate the BAL cellular population. ODTS needs to be clinically distinguished from hypersensitivity pneumonitis (HP), which is also provoked by inhaled organic dusts. Development of HP usually requires repeated exposures, although it can occur following a single acute exposure. Onset may follow such an exposure or may be insidious. HP may result in permanent pulmonary sequelae following even a single occurrence. Unlike with ODTS, the chest X-ray often shows infiltrates, severe hypoxemia, prior sensitization to antigens in the organic dust and there may be significant sequelae in HP. HP is also usually associated with a positive precipitin test and provocation testing may be helpful in diagnosis. The early BAL findings in ODTS are overwhelmingly neutrophilic, unlike the lymphocytic findings in HP. Treatment of ODTS is symptomatic. Unlike with HP, corticosteroids appear to be of only marginal benefit in the treatment of ODTS.

SMOKE INHALATION LUNG INJURY

Smoke inhalation injury, either by itself or in the presence of a burn, is now well-recognized to result in severe lung-induced morbidity and mortality. The most common cause of death in burn centers is respiratory failure.[88-90] The composition of smoke, which leads to lung injury, varies according to the materials that are involved. Common components of smoke are carbon dioxide, carbon monoxide, hydrogen cyanide, oxygen radicals, ammonia, sulfur dioxide, aldehydes, acrolein, aromatic hydrocarbons and phosgene. Carbon monoxide toxicity is one of the leading causes of death in fires.[91,92] Whereas oxygen is used during combustion, carbon monoxide is released, because it is a basic byproduct of combustion.[93] Carbon monoxide is rapidly transported across the alveolar membrane and preferentially binds with the hemoglobin molecule in place of oxygen. In addition, carbon monoxide shifts the hemoglobin-oxygen dissociation curve to the left, thereby impairing oxygen unloading at the tissue level. The result is a major impairment in oxygen delivery.

Direct heat injury caused by the inhalation of air heated to a temperature 150°C or higher ordinarily results in burns to the face, oropharynx and upper airways (above the vocal cords). Even superheated air is rapidly cooled before reaching the lower respiratory tract because of the tremendous heat-exchanging efficiency of the oropharynx and nasopharynx. Heat and especially the chemicals in smoke produce an immediate injury to the airway mucosa, resulting in edema, erythema and ulceration. Although these mucosal changes may be anatomically present shortly after the burn, physiologic alteration may not be present until the edema is sufficient to produce clinical evidence of impaired upper-airway patency. This may not occur for 12 to 18 hours. The presence of a body burn magnifies the injury in direct proportion to the size and depth of the skin burn.[94-96] The epithelial cells in the pharynx respond by increasing mucus production, which can then be found in the lower airways often in obstructive mucus clots. Another compounding injury is any face or neck burn that will produce marked anatomic distortion and in the case of the deep neck burn, external compression on the larynx. A more superficial burn causes massive external edema, but may produce much less mucosal edema and airway compromise. The local edema usually resolves in four to five days. Exposed individuals present with symptoms of obstruction, namely, stridor, dyspnea, increased work of breathing and eventually cyanosis.

Smoke is composed of two phases: a gas and a particle phase. The gas phase contains a number of volatile water-soluble compounds, such as acrolein, chlorine, hydrochloric acid, sulfur compounds, as well as carbon monoxide, carbon dioxide and cyanide gas.[97] Large quantities of short-acting oxidants and oxidant precursors are also present. These compounds have been reported to produce proximal airway damage. The gas phase of smoke also contains unusually long-acting oxidants, which can reach distal lung tissues. These agents produce local-airway injury. The vapors, in large part, are mucus membrane irritants leading to intense bronchorrhea, bronchoconstriction and airway edema. The process often peaks hours after injury, although patients with pre-existing airway reactivity can develop very early intense bronchoconstriction.[98,99] The particle phase of smoke is composed of carbon particles, 0.1 to 10 µm in diameter, on which are adherent many of the compounds found in the gas phase along with heavy metals and other oxygen radical-producing compounds and lipid-soluble compounds like the aldehydes.

Some of the gas compounds like phosgene can also bind to the carbon. Particle size and tidal volume determine their distribution in proximal versus distal lung. Once particles adhere to lung tissue, the injury from adherent toxins, including oxidant release, can occur over hours to days, resulting in progressive cellular injury and in case of severe injuries, mucus membrane destruction can occur. The particles phase injury of smoke produces severe injury. The degree of exposure to the lung is dependent on particle size and breathing pattern.[100] The degree of deposition in distal lung is accentuated by deeper breaths, as would be evident in a hypoxic patient or a patient attempting to actively escape the insult. As opposed to the gas phase, which is short-lived, the particulates can adhere to the mucosa and perpetuate the local tissue injury. Particulate clearance, in turn, is impeded by the impaired mucociliary action perpetuating the injury. Consequent to smoke inhalation injury, there is clinical evidence of continued respiratory compromise namely, dyspnea, tachypnea, diffuse wheezing and rhonchi, which precede radiographic changes. The evidence on radiography of lung damage is usually that of diffuse atelectasis, pulmonary edema or bronchopneumonia.

APPROACH TO A VICTIM OF INHALATION INJURY

Accurate history is of great help for diagnosing the type of inhalation injury in order to find the likely agent/chemical involved and for anticipating the complications accordingly. Depending on the type of presentation, the person can be classified as acutely ill or stable.[101] Acutely ill person will require battery of tests, such as arterial blood gas analysis, chest roentgenogram, blood and urine levels of suspected chemical (e.g. mercury, zinc, etc.), CT scan and bronchoscopy. In case of person being stable clinically, he can undergo pulmonary function tests in addition to the above tests, which can help in diagnosing RADS and bronchiolitis obliterans.

MANAGEMENT

The victim has to be removed immediately from the site of leakage or fire so as to minimize the exposure and to characterize the agents involved.[102] This is followed by thorough decontamination by removing all clothing, which has trapped chemicals in it. If they are outdoors, they should move away from the source of contamination till they reach a safe place. If they are indoors, close all doors and windows and shut down all heating and cooling systems to minimize the entry of contaminants from outside. Individuals suspected to be exposed to chemical contaminants should immediately remove the contaminated clothing and should be irrigated with water and washed with soap and water.[103] The victim is then assessed for the signs of severe injury, which include altered mental status, respiratory insufficiency, cardiovascular instability, convulsions and unconsciousness.

Initial supportive therapy should be focused on airway patency, ventilation and circulation. At the same time, patient must be examined for burns, trauma and other injuries. When poisoning by chemicals is suspected, routine emergency guidelines should be followed which include consideration towards administration of naloxone to patients who have an altered mental status and respiratory depression. Some chemicals cause systemic intoxication and may require treatment with antidotes.[103] Diazepam, cyanide antidote kits, atropine and pralidoxime are the most important drugs, which should be present for managing such emergencies. Airway compromise and respiratory insufficiency may warrant high flow oxygen, intubation or tracheostomy. Patients going into ARDS will require mechanical ventilation as per the ARDS protocol, including low tidal volume, high frequency ventilation. Inhaled or systemic corticosteroids and inhaled bronchodilators are useful in the management of bronchospasm.

Drug-Induced Respiratory Disease

William J Martin II

INTRODUCTION

Drug-induced respiratory disease is it sufficiently common that clinicians need to consider in the differential diagnosis of most acute and chronic respiratory and pleural disorders. The challenge is to consider its possibility when taking the history of the patient. If a good history is not taken and the possibility of drug-induced respiratory disease not considered, the diagnosis is invariably missed and a potentially reversible respiratory disorder can become chronic and lead to progressive disability and death. Thus, despite the various diagnostic clues from tests and imaging modalities, there is nothing more important in making the diagnosis of drug-induced respiratory disease than an accurate history of medication use and the consideration that the medication use might be the cause of the respiratory distress.

There are more than 300 drugs associated with respiratory toxicity[1] and the list is only going to grow as more therapeutic agents are brought to the market. Clinicians often rely on their personal experience or those of their colleagues to suspect the possibility of a drug-induced lung reaction. As noted above, this is the most important step in the diagnosis and management of patients with adverse drug reaction involving the respiratory system. In the past, a clinician might review several of the excellent textbooks or recent reviews to see if an association exists between a specific medication and respiratory toxicity.[1-5] Today, it is much simpler with access to the web site www.pneumotox.com[6] for an excellent and easy method to access up-to-date information on drug-induced lung reactions.

Thus, this chapter will not focus on presenting an exhaustive list of drugs or medications associated with adverse respiratory reactions as those lists are available elsewhere and are everchanging; rather, the chapter will provide an approach focused on certain drug classes known to cause lung disease, specific examples of drugs that illustrate the typical clinical presentation and finally, an approach to clinical management that can be adapted to the evaluation of most patients who present with symptoms or findings, consistent with drug-induced respiratory disease.

DRUGS ASSOCIATED WITH RESPIRATORY TOXICITY

Cancer Chemotherapy Agents

There are several ways to organize one's approach to the assessment of drug-induced respiratory toxicity. Although the list of possible drugs that cause adverse lung and pleural reactions is long, one can organize the drugs into broad categories that reflect their general class of use (Table 114.1). From this, one can find well-described examples of the most common adverse drug reactions that most clinicians will see during the course of their professional career.

Cancer chemotherapeutic agents, including radiation were among the first class of drugs or agents to be recognized as cause of respiratory toxicity (Table 114.2). Busulfan, one of the early alkylating agents, was first described in 1970s as a cause of diffuse lung disease, leading to progressive fibrosis and death.[7,8] Since then, many cancer chemotherapy agents have been implicated

in respiratory toxicity, not only complicating the cancer treatment regimen, but limiting additional therapeutic approaches to controlling cancer growth.[9,10] Thus, the need to understand the mechanisms of chemotherapy-induced lung disease is critical to provide better strategies to maximize the antitumor effect and to minimize the pulmonary complications for the patient (Fig. 114.1).

One of the typical examples of respiratory toxicity from cancer chemotherapy occurs with bleomycin, an antibiotic derived from *Streptomyces verticillus*, which is an effective cancer chemotherapy agent, especially for germ cell tumors of the testes and lymphomas.[11-13] It has been recognized since the 1960s that the drug can generate oxygen radicals and damage deoxyribonucleic acid (DNA)[13] (Fig. 114.2). This property makes it effective to kill cancer cells, but may also serve to injure critical alveolar lining cells and endothelial cells in the lung, which may result in acute lung injury and death. This process may account for the reported postoperative

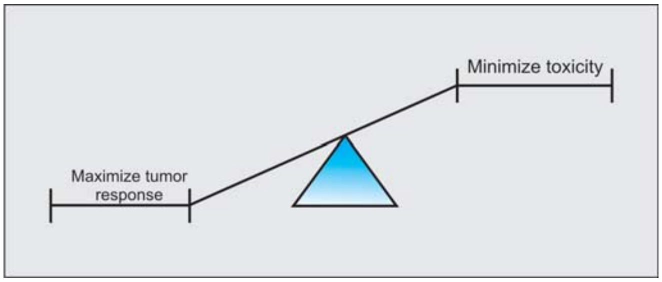

Fig. 114.1: Therapeutic strategy for cancer chemotherapy

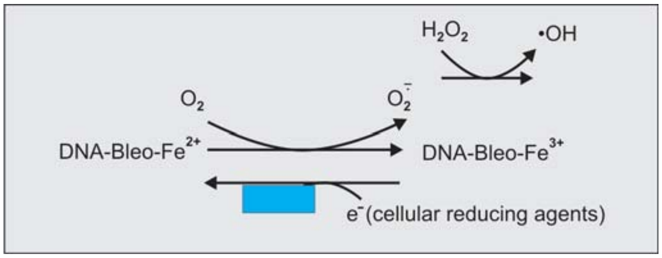

Fig. 114.2: Effect of iron-containing bleomycin on oxygen radical generation

Acute respiratory distress syndrome (ARDS) occurring in patients who have previously received bleomycin.[14,15] Additionally, bleomycin pulmonary toxicity may be associated with an acute inflammatory or immune response in the lung, further comprising lung function. The ability of drugs to cause both direct toxic and indirect inflammatory-mediated lung injury is common to many drugs in the class of cancer chemotherapy agents. Each drug may be unique in how the initial injury occurs and where it occurs in the respiratory system, but the complexity of the mechanisms and the repair responses in the lung often undermine a predictable course for any given patient.

Brief Case Report: A 23-year-old male with a history of embryonal cancer of the testes has received four courses of VP-16, cisplatinum and bleomycin. The patient presented to the emergency room of the hospital with high fevers and abdominal pain. His admission chest X-ray was normal and at laparotomy, he was found to have a bowel infarction. He developed hypoxemia post-operatively that required mechanical ventilation, positive end-expiratory pressure (PEEP) and an increase in the FiO_2 from 0.4 to 0.7. The patient developed diffuse lower lobe infiltrates. There was no evidence of fluid imbalance and a lung biopsy was performed to rule out complicating infection and revealed findings consistent with bleomycin toxicity.

Lessons Learned: Always consider bleomycin toxicity in any individual who develops respiratory distress and has received bleomycin at any time. It is possible that the acute onset of bleomycin toxicity in this patient was precipitated by the surgery and the use of supplemental oxygen postoperatively. Oxygen clearly exacerbates bleomycin toxicity in animal or cellular models, but its impact in human subjects is less clear and it is important to be prudent in patients that have received bleomycin and to avoid any unnecessary supplemental O_2.

Cardiovascular Drugs

Cardiac medications have been implicated as often a rare, but important class of drugs associated with pulmonary toxicity. For example, methyldopa, commonly used to treat hypertension, was one of the first drugs associated with systemic and immunologic findings consistent with drug-induced lupus syndrome.[16] Similarly, procainamide and hydralazine was also recognized for this side effect. Development of a positive immunologic parameter, such as the antinuclear antigen (ANA) may occur with therapy on such drugs, but this is not necessarily that a systemic drug response will occur nor does it mean that therapy should be altered. It occurs commonly with a conversion rate of 40 to 60% of patients on treatment. The drug-induced lupus syndrome, however, can be serious and life threatening.

In the more recent past, the cardiovascular drug amiodarone has become an important cause of pulmonary toxicity with multiple reports and studies documenting the varied clinical presentations and findings.[17-19] Amiodarone is an unusual drug as it is an iodinated benzofuran derivative and its primary metabolite is created by the liver conversion of desethylamiodarone by the removal of an ethyl group from the parent compound. The drug has a very long pharmacologic half-life of approximately 45 days and both, the parent drug and its metabolite, will persist long after the drug is discontinued.[18,19] Amiodarone was used in Europe for decades before approval for use in the USA and the pulmonary toxicity was not recognized until studied in the USA. This may, in part, relate to the higher doses used in the US as it was initially approved for use with only life-threatening rhythm disturbances that typically required higher doses (600 to 800 mg/day). However, since that time, amiodarone pulmonary toxicity has been well recognized to occur with lower doses of the drug (200 to 400 mg/day) throughout the world, although the toxicity is more common with higher dosages. It also appears to typically require several weeks or months of treatment before symptoms or signs of pulmonary toxicity become apparent.

For patients with a history of congestive heart failure and rhythm abnormalities, the onset of dyspnea or cough or signs of new infiltrates on a chest X-ray might easily be attributed to the underlying cardiac condition. Most typically, amiodarone pulmonary toxicity occurs insidiously with cough, dyspnea, weight loss and evidence of progressive interstitial disease. Another form of toxicity may occur acutely with more of an alveolar pattern and can be localized or diffuse. If associated with pleuritic chest pain, the diagnosis can be confused with acute pulmonary embolism, a condition to be suspected in anyone with a diminished cardiac output. Another form of toxicity mimics Bronchiolitis Obliterans with Organizing Pneumonia (BOOP) that may present with a typical unilateral and pleural-based mass-like lesion.

Lung function testing with diffusing capacity for CO (DL_{co}) often reveals restrictive changes and a low DL_{co} in patients with pulmonary toxicity. However, this may not be as helpful as you would think as a screening tool for toxicity. Similar findings of a decrease in the DL_{co} may occur in otherwise asymptomatic patients taking amiodarone and this does not appear to predict risk of toxicity.

Bronchoscopy is often considered in the evaluation of patients with suspected amiodarone pulmonary toxicity. Both Bronchoalveolar Lavage (BAL) and transbronchosopic lung biopsy can be useful to support the diagnosis or perhaps more importantly to help in excluding other diagnostic possibilities, such as infection or cancer. Bronchoalveolar Lavage in almost all subjects, receiving amiodarone, will show the typical findings of "foamy macrophages"[17-19] whereas, this is quite a characteristic of amiodarone use. This is not a diagnostic of toxicity but rather simply a marker of "drug effect". In contrast, a marked lymphocytosis of $CD8^+$ lymphocytes (typically >40% of BAL cells) may indicate a hypersensitivity reaction. Similarly, the lung biopsy is often nondiagnostic, revealing the typical "foamy macrophages" that again provides evidence that the subject is taking amiodarone but does not necessarily indicate that toxicity is present.

Antibiotics/Antimicrobials

Pulmonary toxicity from antibiotic usage is rare, but since antibiotic or antimicrobial use is so common, it becomes one of the most important classes of drugs to consider as a cause of drug induced lung disease (Table 114.3). Nitrofurantoin toxicity is one of the best described and oldest examples of an antibiotic that can cause severe pulmonary-pleural reactions.[20,21] Nitrofurantoin remains a highly effective antibiotic for urinary tract infections and particularly for those with recurrent urinary infections who require chronic suppression or prophylaxis. For subjects who are taking nitrofurantoin for many years, they are often forgetful about reporting it among their list of medications. This is why the diagnosis of chronic nitrofurantoin toxicity is often missed.

TABLE 114.3: Antibiotic agents

- Nitrofurantoin
- Azulfidine
- Sulfonamides
- Gentamicin
- Neomycin
- Polymyxin
- Colistin
- Streptomycin
- INH, PAS
- Minocycline

Nitrofurantoin pulmonary toxicity can also occur acutely even after the first dose and this can appear with sudden onset of cough and dyspnea and a chest X-ray that has diffuse alveolar infiltrates with or without pleural effusions and may mimic the appearance of congestive heart failure. Occasionally, a patient with acute onset may have a high peripheral blood eosinophil count and this can be an important clue to the diagnosis. In some cases, the peripheral blood changes may be normal or with only slightly elevated eosinophil count, but the BAL may show marked eosinophilia (>30% of total cells). If the onset is acute, simply discontinuation of the drug can bring a prompt recovery of the patient with normalization of the chest X-ray or symptoms in just a few days.

In contrast, chronic nitrofurantoin toxicity may mimic the clinical and roentgenographic presentation of Idiopathic Pulmonary Fibrosis (IPF). The concern in this case is that a missed diagnosis of chronic nitrofurantoin toxicity may result in a patient being given the diagnosis of IPF that is essentially a fatal disease over the course of a few years and for which there is no currently effective therapy outside of lung transplantation. Unlike IPF, corticosteroids hasten recovery from the fibrotic like condition of nitrofurantoin toxicity and if instituted early in the course, the patient can expect a full recovery.

Similar to the case of bleomycin above, nitrofurantoin can generate toxic O_2-derived radicals[22] and similarly, the toxicity can be exacerbated in the presence of hyperoxia. Overzealous use of supplemental O_2 can exacerbate the underlying lung injury and convert a mild case of toxicity into a life-threatening event.

There are many other examples of antibiotic-induced lung toxicity but the following case presentation illustrates a typical example and as noted, the antibiotic may not have been given for a serious medical condition or even as the best available treatment for the condition. At times, our comfort with the use of antibiotics as benign therapies in our outpatient clinical practice masks our scrutiny of these therapies as potentially harmful and even life-altering adverse reactions. This is one example.

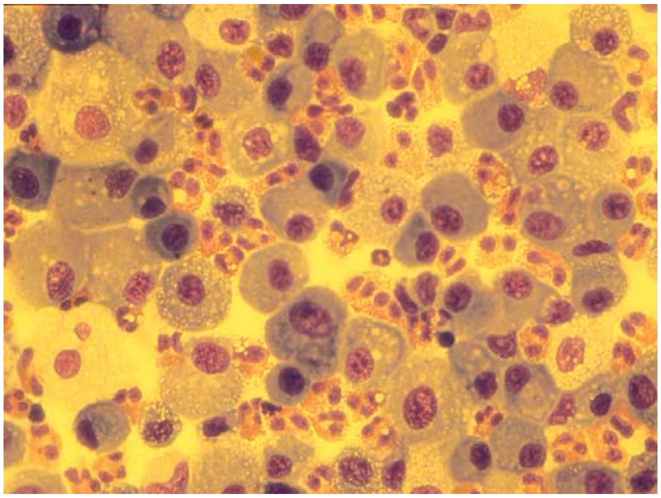

Fig. 114.3: Eosinophilic pneumonia

Brief Case Report: A 17-year-old female athlete (nationally competitive at basketball and running track) presented with a few days of malaise, low-grade fever and light headedness. She developed dyspnea while playing a basketball game and collapsed in the shower after the game. The following day she had dyspnea at rest and a temperature of 39.5°C. A chest X-ray in the emergency room revealed bilateral and peripheral alveolar infiltrates. She was admitted to the hospital and a BAL (Fig. 114.3) and open lung biopsy revealed findings consistent with eosinophilic pneumonia. She was started on oral corticosteroids and tapered over six weeks with modest improvement. She was referred for further evaluation to a pulmonary specialist. Her history revealed that she was started on an antibiotic for "acne and complexion problems," three weeks prior to the onset of her symptoms. On further review, she was found to have taken sulfamethoxazole/trimethoprim, which had not been discontinued despite the hospitalization. Two months after the onset of symptoms, the drug was discontinued and the patient was started on prednisone 60 mg a day for six weeks and with a slow taper of the prednisone dose over six months. Her predicted Forced Vital Capacity (FVC) was 4.65L but when tested at the time of referral was only 2.41L. Six months later, on prednisone 10 mg/ day, her FVC had partially improved to 3.4L. Her chest X-ray had persistent interstitial changes at the bases. She was asymptomatic at rest but was unable to exercise at her prior level of activity and had lost the opportunity to receive an athletic scholarship to a university. Her symptoms and lung functions were unchanged one year later.

Lessons Learned: Always take a complete history on medication use, as any recent medication prior to the onset of a respiratory illness should raise suspicions of a drug-induced respiratory toxicity. Discontinue any medication immediately that is not absolutely necessary if the cause of the respiratory illness is unknown. Eosinophilic pneumonia should always raise the possibility of an environmental source of the pneumonitis, and drug or medication use should be a first consideration. Delays in diagnosis and proper treatment may result in permanent loss of lung function. For a young woman of 17, this was a considerable loss and yet was likely preventable.

Anti-Inflammatory and Miscellaneous Drugs

Several anti-inflammatory agents are associated with respiratory toxicity (Table 114.4). Classically, an overdose with aspirin can result in acute pulmonary edema and marked changes in the acid base balance in the blood, contribute to further respiratory distress.[23] Use of gold salts in rheumatoid arthritis remains a useful therapy for severe diseases and is well recognized as a cause of interstitial lung disease.[24] Clinically, the confusion about the cause of the interstitial changes occurs because rheumatoid disease is also a known cause of interstitial lung disease and it may be difficult to know if the gold or the underlying disease is responsible for the progression of the respiratory disease. Helpful guidelines have been provided to suggest the possibility of a drug reaction, including a fever, skin rash, absence of subcutaneous nodules and more of an alveolar pattern on the chest X-ray.[24] Ofcourse, from a practical perspective, if discontinuation of the gold therapy is possible and results in significant improvement in the symptoms and findings, that would be strongly suggestive that the gold therapy was the source of the respiratory distress.

Penicillamine is another interesting drug that has both chelating and immunosuppressive properties. Its use, primarily as an immunosuppressive agent, in rheumatoid arthritis has been associated with different types of adverse pulmonary reactions, including: (1) Organizing pneumonia, (2) drug-induced lupus syndrome or (3) alveolar hemorrhage.[25] As therapeutic alternatives to penicillamine become increasingly available, it is likely that adverse reactions to this older therapy will become less frequent. However, penicillamine remains an important chelating agent for diseases, such as Wilson's disease and like many therapies; penicillamine may have "second lives" as new indications are found for this therapy from the 1950s.

TABLE 114.4: Anti-inflammatory agents

A variety of miscellaneous drugs not easily put into a single class of drugs or agents also cause lung disease (Table 114.5). For example, there are excellent reviews of how illicit drugs can be a cause of adverse reactions in the respiratory system, including heroin or other narcotic drugs, cocaine and marijuana.[26] In addition, tocolytics, such as oxytocin can induce uterine contractions and thereby prevent postpartum hemorrhage.[27] A diverse number of drugs can cause a drug-induced lupus syndrome, which can mimic systemic lupus erythematosis, including hydralazine, penicillamine, alpha methyldopa, procainamide, various anticonvulsants and more recently anti-tumor necrosis factor (TNF) antibody therapy.[28,29]

DIAGNOSIS AND MANAGEMENT OF DRUG-INDUCED RESPIRATORY DISEASE

As noted in the introduction, there is nothing more important in the diagnosis of drug-induced respiratory disease than an accurate history and recognition that a medication or drug might be the cause of the respiratory distress. If that key-step is missed, all the subsequent testing and evaluation may not establish the link and may not make the correct diagnosis in your patient.

The standard diagnostic approach includes everything from a history and exam to a lung biopsy, if necessary (Table 114.6). Obviously, chest imaging with a chest X-ray and chest computerized tomography often

TABLE 114.6: Diagnostic approaches

- Bronchoscopy (biopsy, BAL)
- VATS or open lung biopsy

provide critical information regarding the pattern and extent of the disease and many provide enough information to establish a "working diagnosis" of a drug reaction.[30-32] Pulmonary function tests can be helpful in confirming the typical findings of a restrictive pattern with a decrease in the diffusing capacity, although some drugs may induce obstructive changes whereas others do not affect diffusing capacity. The Pulmonary function tests (PFTs) can also be abnormal prior to the onset of symptoms and do not necessarily indicate clinical disease or clinical progression. Many patients have more than one reasonable explanation for the diagnosis and may require a more invasive approach including a lung biopsy.

Flexible fiberoptic bronchoscopy remains a very useful tool in the assessment of patients with suspected drug-induced respiratory disease. Bronchoalveolar lavage can strongly suggest certain diagnoses, such as eosinophilic pneumonia (Fig. 114.3) or hypersensitivity pneumonitis if there is an exuberant number (>40% of total cells), representing CD8$^+$ (suppressor/cytotoxic) lymphocytes. In addition, bronchoscopy with transbronchoscopic lung biopsy and BAL can help in assessing the presence of other conditions, such as complicating infection, underlying respiratory disease (for which the patient might be receiving the drug) or metastatic cancer.

However, even after completion of all available diagnostic tests, the clinician might remain uncertain if the patients' symptoms reflect a case of drug-induced respiratory disease. Under these circumstances, one can consider all of the information to indicate whether supportive evidence exists or whether careful assessment of the patient's status following drug withdrawal is the best approach (Table 114.7). Many patients respond quickly to the withdrawal of a drug causing the lung reaction but if the symptoms have been present for weeks or months, the response may be slow. Under these circumstances or if the patient is severely ill, many clinicians would favor a course of corticosteroids in addition to the drug withdrawal, as it will hasten recovery and will be reassuring to both the patient and the clinician that the diagnosis was correct.

TABLE 114.7: Verification of diagnosis

- Supportive evidence from lung biopsy or BAL material (also important for exclusion of other diagnosis)
- Improvement in subjective and objective parameters following drug withdrawal
- Rechallenge with drug reproduces findings (rarely indicated)

Even after all of the above, at times the clinician might consider a rechallenge with the drug suspected of causing the reaction, but this is rarely indicated. A rechallenge might only be considered if the drug suspected (but not proven) of causing the lung reaction is the only available therapy for a life-threatening condition. One example in my own experience was a case of suspected amiodarone pulmonary toxicity for a patient with a history of life-threatening ventricular rhythm disturbances. In this case, stopping the drug promptly increase the ventricular rhythm abnormalities. We were uncertain of the diagnosis and elected to rechallenge the patient in the intensive care unit setting. The patient did not show signs of any respiratory distress and resumed full therapy without incident.

There are often no easy answers in the management of patients with suspected drug-induced respiratory disease. One must have the discipline to understand clearly the rationale for each test ordered and what you would do with the information when it is available regarding the management of the patient. Obviously, if the history, exam and chest imaging suffices to establish a "working diagnosis", then drug withdrawal with or without corticosteroids may be the best approach. In some patients, a clear definitive answer is not available even after an open lung biopsy. In such cases, clinical judgment is necessary to determine, if drug withdrawal is best to assess its impact on the patients symptoms and findings. As noted above, the need for a rechallenge with a drug is rarely indicated as almost always, there are alternative therapies available for the patient and there is no justification for a rechallenge, which in itself can be life-threatening. As the dictum in medicine is that "primum non nocere" or "first, do not harm", it is highly unlikely that there will be clinical circumstances that a clinician should seriously consider a rechallenge. There are almost always other therapies available that will provide safe and effective therapy for your patient.

Epidemiology and Etiopathogenesis of Lung Cancer

Navneet Singh

INTRODUCTION

Lung cancer is the most common malignant neoplasm world over.[1] It accounts for more cancer deaths than any other cancer.[2] Impressive advances have been made in relation to the understanding of the pathogenesis of lung cancer over the past few decades.[3] Tobacco smoke remains the most important risk factor and etiological agent for its development. In addition, several other environmental and occupational carcinogens have been identified. Genetic factors which determine susceptibility to this disease continue to be evaluated. There has also been a steady improvement in the understanding of the pathogenesis of this disease at the molecular level, including progression from normal respiratory epithelium to frank neoplastic cells as well as changes observed after this transition (survival, growth and proliferation of cancerous cells). This has important implications in terms of early detection and chemoprevention of the disease.

EPIDEMIOLOGY

Lung cancer is the most common cancer representing approximately 12% of all new cancers.[1] It is also the most frequent type of cancer in males and remains the most common cause of cancer related mortality in both sexes.[2] Most patients present with an advanced disease.[4]

Distribution of Various Histological Type

The major histological types of lung cancer include Squamous Cell Carcinoma (SqCC), Adenocarcinoma (ADC) and Small Cell Lung Cancer (SCLC).

In the recent past, a relative increase in the incidence of ADC has been witnessed. In most of the developed countries, it has become the dominant histological type of lung cancer.[5,6] It has also overtaken SqCC as the most common form of lung cancer among males in some countries while it has continued to be the commonest type among females.[6] A compilation of population-based lung cancer incidence data from registries contributing to the International Agency for Research on Cancer (IARC) databases revealed that rates of all lung cancer types among women and of ADC among men had risen despite a decline in cigarette use in many Western countries as well as a shift to filtered and low-tar cigarettes.[7]

Incidence rates for SqCC declined by 30% or more among males in North America and some European countries while the decline in those for SCLC was less pronounced. On the other hand, among females, incidence rates for both SqCC and SCLC showed an increase in most of the regions. Importantly, the incidence of ADC increased among both sexes in virtually all areas.

Link between Histology and Smoking

This histological shift (increase in the incidence of ADC) in the developed countries has been linked to changes in the smoking behavior of the population in these regions as well as in the method of manufacturing and composition of cigarettes being marketed therein.[8,9] Use of cigarettes that had filters as well as a lower content of tar and nicotine resulted in a tendency for their smoke to be inhaled more deeply.[10] This led to a higher concentration of carcinogens in the peripheral areas of the

TABLE 115.1: Lack of change in the epidemiological profile of lung cancer in North India (modified and adapted from Singh et al)[13]

Period of data collection	*1977-86*	*2007-09*
Number of cases	1009	250
Mean [±SD] age (years)	54.3 [*]	57.9 [±11.3]
Male: female	4.48 : 1	4.43 : 1
Smokers**: never-smokers	2.68 : 1	2.67 : 1
Major histological types		
• Squamous cell	34.3%	34.8%
• Adenocarcinoma	25.9%	26.0%
• Small cell	20.3%	18.4%

SD = Standard deviation
* SD not mentioned
** Includes both current smokers and ex-smokers

lungs where ADC tends to form.[11] Higher levels of nitrates in the tobacco blends used in cigarette manufacturing have also been linked to the development of ADC.[12]

However, in a recent analysis of temporal trends conducted at the author's institute, no significant change was observed in the epidemiology of lung cancer as compared to that seen three decades ago (Table 115.1).[13] Squamous cell carcinoma was the most common histological type overall as well as among patients who were current/ex-smokers. Adenocarcinoma was the predominant histological type only among never-smokers. Data available from the population based National Cancer Registry Program (NCRP) of India was analyzed to determine the trends in incidence rates of 10 major cancers over a period of almost two decades (1982 to 2000).[14] Here also, no significant changes were observed, during the study period, in relation to lung cancer. However, there was no data about the distribution of different histological types of lung cancer.
